A request to the `Movies` controller returns all the entries in the `Movies` table of the movie database and then passes the results to the `Index` view.

Strongly Typed Models and the @model Keyword

Earlier in this tutorial, you saw how a controller can pass data or objects to a view template using the `ViewBag` object. The `ViewBag` is a dynamic object that provides a convenient late-bound way to pass information to a view.

ASP.NET MVC also provides the ability to pass strongly typed data or objects to a view template. This strongly typed approach enables better compile-time checking of your code and richer IntelliSense in the Visual Web

Developer editor. We're using this approach with the `MoviesController` class and *Index.cshtml* view template.

Notice how the code creates a `List` object when it calls the `View` helper method in the `Index` action method. The code then passes this `Movies` list from the controller to the view:

```
public ViewResult Index()
{
    return View(db.Movies.ToList());
}
```

By including a `@model` statement at the top of the view template file, you can specify the type of object that the view expects. When you created the movie controller, Visual Web Developer automatically included the following `@model` statement at the top of the *Index.cshtml* file:

```
@model IEnumerable<MvcMovie.Models.Movie>
```

This `@model` directive allows you to access the list of movies that the controller passed to the view by using a `Model` object that's strongly typed. For example, in the *Index.cshtml* template, the code loops through the movies by doing a `foreach` statement over the strongly typed `Model` object:

```
@foreach (var item in Model) {
    <tr>
        <td>
            @Html.DisplayFor(modelItem => item.Title)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.ReleaseDate)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Genre)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Price)
        </td>
        <td>
            @Html.ActionLink("Edit", "Edit", new { id=item.ID }) |
            @Html.ActionLink("Details", "Details", new { id=item.ID }) |
            @Html.ActionLink("Delete", "Delete", new { id=item.ID })
        </td>
    </tr>
}
```

Because the `Model` object is strongly typed (as an `IEnumerable<Movie>` object), each `item` object in the loop is typed as `Movie`. Among other benefits, this means that you get compile-time checking of the code and full IntelliSense support in the code editor:

Working with SQL Server Compact

Entity Framework Code First detected that the database connection string that was provided pointed to a `Movies` database that didn't exist yet, so Code First created the database automatically. You can verify that it's been created by looking in the *App_Data* folder. If you don't see the *Movies.sdf* file, click the **Show All Files** button in the **Solution Explorer** toolbar, click the **Refresh** button, and then expand the *App_Data* folder.

Double-click *Movies.sdf* to open **Server Explorer**. Then expand the **Tables** folder to see the tables that have been created in the database.

> **NOTE**
>
> If you get an error when you double-click *Movies.sdf*, make sure you've installed SQL Server Compact 4.0(runtime + tools support). (For links to the software, see the list of prerequisites in part 1 of this tutorial series.) If you install the release now, you'll have to close and re-open Visual Web Developer.

There are two tables, one for the `Movie` entity set and then the `EdmMetadata` table. The `EdmMetadata` table is used by the Entity Framework to determine when the model and the database are out of sync.

Right-click the `Movies` table and select **Show Table Data** to see the data you created.

Right-click the `Movies` table and select **Edit Table Schema**.

Notice how the schema of the `Movies` table maps to the `Movie` class you created earlier. Entity Framework Code First automatically created this schema for you based on your `Movie` class.

When you're finished, close the connection. (If you don't close the connection, you might get an error the next time you run the project).

You now have the database and a simple listing page to display content from it. In the next tutorial, we'll examine the rest of the scaffolded code and add a `SearchIndex` method and a `SearchIndex` view that lets you search for movies in this database.

Examining the Edit Methods and Edit View (C#)

9/16/2020 • 14 minutes to read • Edit Online

by Rick Anderson

> **NOTE**
>
> An updated version of this tutorial is available here that uses ASP.NET MVC 5 and Visual Studio 2013. It's more secure, much simpler to follow and demonstrates more features.

This tutorial will teach you the basics of building an ASP.NET MVC Web application using Microsoft Visual Web Developer 2010 Express Service Pack 1, which is a free version of Microsoft Visual Studio. Before you start, make sure you've installed the prerequisites listed below. You can install all of them by clicking the following link: Web Platform Installer. Alternatively, you can individually install the prerequisites using the following links:

- Visual Studio Web Developer Express SP1 prerequisites
- ASP.NET MVC 3 Tools Update
- SQL Server Compact 4.0(runtime + tools support)

If you're using Visual Studio 2010 instead of Visual Web Developer 2010, install the prerequisites by clicking the following link: Visual Studio 2010 prerequisites.

A Visual Web Developer project with C# source code is available to accompany this topic. Download the C# version. If you prefer Visual Basic, switch to the Visual Basic version of this tutorial.

In this section, you'll examine the generated action methods and views for the movie controller. Then you'll add a custom search page.

Run the application and browse to the `Movies` controller by appending */Movies* to the URL in the address bar of your browser. Hold the mouse pointer over an **Edit** link to see the URL that it links to.

The **Edit** link was generated by the `Html.ActionLink` method in the *Views\Movies\Index.cshtml* view:

```
@Html.ActionLink("Edit", "Edit", new { id=item.ID })
```

The `Html` object is a helper that's exposed using a property on the `WebViewPage` base class. The `ActionLink` method of the helper makes it easy to dynamically generate HTML hyperlinks that link to action methods on controllers. The first argument to the `ActionLink` method is the link text to render (for example, `<a>Edit Me</a>`). The second argument is the name of the action method to invoke. The final argument is an anonymous object that generates the route data (in this case, the ID of 4).

The generated link shown in the previous image is `http://localhost:xxxxx/Movies/Edit/4`. The default route takes the URL pattern `{controller}/{action}/{id}`. Therefore, ASP.NET translates `http://localhost:xxxxx/Movies/Edit/4` into a request to the `Edit` action method of the `Movies` controller with the parameter `ID` equal to 4.

You can also pass action method parameters using a query string. For example, the URL `http://localhost:xxxxx/Movies/Edit?ID=4` also passes the parameter `ID` of 4 to the `Edit` action method of the `Movies` controller.

Open the `Movies` controller. The two `Edit` action methods are shown below.

```
//
// GET: /Movies/Edit/5

public ActionResult Edit(int id)
{
    Movie movie = db.Movies.Find(id);
    return View(movie);
}

//
// POST: /Movies/Edit/5

[HttpPost]
public ActionResult Edit(Movie movie)
{
    if (ModelState.IsValid)
    {
        db.Entry(movie).State = EntityState.Modified;
        db.SaveChanges();
        return RedirectToAction("Index");
    }
    return View(movie);
}
```

Notice the second `Edit` action method is preceded by the `HttpPost` attribute. This attribute specifies that overload of the `Edit` method can be invoked only for POST requests. You could apply the `HttpGet` attribute to the first edit method, but that's not necessary because it's the default. (We'll refer to action methods that are implicitly assigned the `HttpGet` attribute as `HttpGet` methods.)

The `HttpGet` `Edit` method takes the movie ID parameter, looks up the movie using the Entity Framework `Find` method, and returns the selected movie to the Edit view. When the scaffolding system created the Edit view, it examined the `Movie` class and created code to render `<label>` and `<input>` elements for each property of the class. The following example shows the Edit view that was generated:

```
@model MvcMovie.Models.Movie

@{
    ViewBag.Title = "Edit";
}

<h2>Edit</h2>

<script src="@Url.Content("~/Scripts/jquery.validate.min.js")" type="text/javascript"></script>
<script src="@Url.Content("~/Scripts/jquery.validate.unobtrusive.min.js")" type="text/javascript"></script>

@using (Html.BeginForm()) {
    @Html.ValidationSummary(true)
    <fieldset>
        <legend>Movie</legend>

        @Html.HiddenFor(model => model.ID)

        <div class="editor-label">
            @Html.LabelFor(model => model.Title)
        </div>
        <div class="editor-field">
            @Html.EditorFor(model => model.Title)
            @Html.ValidationMessageFor(model => model.Title)
        </div>

        <div class="editor-label">
            @Html.LabelFor(model => model.ReleaseDate)
        </div>
        <div class="editor-field">
            @Html.EditorFor(model => model.ReleaseDate)
            @Html.ValidationMessageFor(model => model.ReleaseDate)
        </div>

        <div class="editor-label">
            @Html.LabelFor(model => model.Genre)
        </div>
        <div class="editor-field">
            @Html.EditorFor(model => model.Genre)
            @Html.ValidationMessageFor(model => model.Genre)
        </div>

        <div class="editor-label">
            @Html.LabelFor(model => model.Price)
        </div>
        <div class="editor-field">
            @Html.EditorFor(model => model.Price)
            @Html.ValidationMessageFor(model => model.Price)
        </div>

        <p>
            <input type="submit" value="Save" />
        </p>
    </fieldset>
}

<div>
    @Html.ActionLink("Back to List", "Index")
</div>
```

Notice how the view template has a `@model MvcMovie.Models.Movie` statement at the top of the file — this specifies that the view expects the model for the view template to be of type `Movie`.

The scaffolded code uses several *helper methods* to streamline the HTML markup. The `Html.LabelFor` helper displays the name of the field ("Title", "ReleaseDate", "Genre", or "Price"). The `Html.EditorFor` helper displays an HTML `<input>` element. The `Html.ValidationMessageFor` helper displays any validation messages associated with that property.

Run the application and navigate to the */Movies* URL. Click an **Edit** link. In the browser, view the source for the page. The HTML in the page looks like the following example. (The menu markup was excluded for clarity.)

```
<!DOCTYPE html>
<html>
<head>
    <meta charset="utf-8" />
    <title>Edit</title>
    <link href="/Content/Site.css" rel="stylesheet" type="text/css" />
    <script src="/Scripts/jquery-1.5.1.min.js" type="text/javascript"></script>
    <script src="/Scripts/modernizr-1.7.min.js" type="text/javascript"></script>
</head>
<body>
    <div class="page">
        <header>
            <div id="title">
                <h1>MVC Movie App</h1>
            </div>
           ...
        </header>
        <section id="main">

<h2>Edit</h2>

<script src="/Scripts/jquery.validate.min.js" type="text/javascript"></script>
<script src="/Scripts/jquery.validate.unobtrusive.min.js" type="text/javascript"></script>

<form action="/Movies/Edit/4" method="post">    <fieldset>
        <legend>Movie</legend>

        <input data-val="true" data-val-number="The field ID must be a number."
    data-val-required="The ID field is required." id="ID" name="ID" type="hidden" value="4" />

        <div class="editor-label">
            <label for="Title">Title</label>
        </div>
        <div class="editor-field">
            <input class="text-box single-line" id="Title" name="Title" type="text" value="Rio Bravo" />
            <span class="field-validation-valid" data-valmsg-for="Title" data-valmsg-replace="true"></span>
        </div>

        <div class="editor-label">
            <label for="ReleaseDate">ReleaseDate</label>
        </div>
        <div class="editor-field">
            <input class="text-box single-line" data-val="true" data-val-required="The ReleaseDate field is
required."
    id="ReleaseDate" name="ReleaseDate" type="text" value="4/15/1959 12:00:00 AM" />
            <span class="field-validation-valid" data-valmsg-for="ReleaseDate" data-valmsg-replace="true">
</span>
        </div>

        <div class="editor-label">
            <label for="Genre">Genre</label>
        </div>
        <div class="editor-field">
            <input class="text-box single-line" id="Genre" name="Genre" type="text" value="Western" />
            <span class="field-validation-valid" data-valmsg-for="Genre" data-valmsg-replace="true"></span>
```

```
        </div>

        <div class="editor-label">
            <label for="Price">Price</label>
        </div>
        <div class="editor-field">
            <input class="text-box single-line" data-val="true" data-val-number="The field Price must be a
number."
    data-val-required="The Price field is required." id="Price" name="Price" type="text" value="9.99" />
            <span class="field-validation-valid" data-valmsg-for="Price" data-valmsg-replace="true"></span>
        </div>

        <p>
            <input type="submit" value="Save" />
        </p>
    </fieldset>
</form>
<div>
    <a href="/Movies">Back to List</a>
</div>

        </section>
        <footer>
        </footer>
    </div>
</body>
</html>
```

The `<input>` elements are in an HTML `<form>` element whose `action` attribute is set to post to the */Movies/Edit* URL. The form data will be posted to the server when the **Edit** button is clicked.

Processing the POST Request

The following listing shows the `HttpPost` version of the `Edit` action method.

```
[HttpPost]
public ActionResult Edit(Movie movie)
{
    if (ModelState.IsValid)
    {
        db.Entry(movie).State = EntityState.Modified;
        db.SaveChanges();
        return RedirectToAction("Index");
    }
    return View(movie);
}
```

The ASP.NET framework model binder takes the posted form values and creates a `Movie` object that's passed as the `movie` parameter. The `ModelState.IsValid` check in the code verifies that the data submitted in the form can be used to modify a `Movie` object. If the data is valid, the code saves the movie data to the `Movies` collection of the `MovieDBContext` instance. The code then saves the new movie data to the database by calling the `SaveChanges` method of `MovieDBContext`, which persists changes to the database. After saving the data, the code redirects the user to the `Index` action method of the `MoviesController` class, which causes the updated movie to be displayed in the listing of movies.

If the posted values aren't valid, they are redisplayed in the form. The `Html.ValidationMessageFor` helpers in the *Edit.cshtml* view template take care of displaying appropriate error messages.

Note about locales If you normally work with a locale other than English, see Supporting ASP.NET MVC 3 Validation with Non-English Locales.

Making the Edit Method More Robust

The `HttpGet` `Edit` method generated by the scaffolding system doesn't check that the ID that's passed to it is valid. If a user removes the ID segment from the URL (`http://localhost:xxxxx/Movies/Edit`), the following error is displayed:

A user could also pass an ID that doesn't exist in the database, such as `http://localhost:xxxxx/Movies/Edit/1234`. You can make two changes to the `HttpGet` `Edit` action method to address this limitation. First, change the `ID` parameter to have a default value of zero when an ID isn't explicitly passed. You can also check that the `Find`

method actually found a movie before returning the movie object to the view template. The updated `Edit` method is shown below.

```
public ActionResult Edit(int id = 0)
{
    Movie movie = db.Movies.Find(id);
    if (movie == null)
    {
        return HttpNotFound();
    }
    return View(movie);
}
```

If no movie is found, the `HttpNotFound` method is called.

All the `HttpGet` methods follow a similar pattern. They get a movie object (or list of objects, in the case of `Index`), and pass the model to the view. The `Create` method passes an empty movie object to the Create view. All the methods that create, edit, delete, or otherwise modify data do so in the `HttpPost` overload of the method. Modifying data in an HTTP GET method is a security risk, as described in the blog post entry ASP.NET MVC Tip #46 – Don't use Delete Links because they create Security Holes. Modifying data in a GET method also violates HTTP best practices and the architectural REST pattern, which specifies that GET requests should not change the state of your application. In other words, performing a GET operation should be a safe operation that has no side effects.

Adding a Search Method and Search View

In this section you'll add a `SearchIndex` action method that lets you search movies by genre or name. This will be available using the */Movies/SearchIndex* URL. The request will display an HTML form that contains input elements that a user can fill in in order to search for a movie. When a user submits the form, the action method will get the search values posted by the user and use the values to search the database.

Displaying the SearchIndex Form

Start by adding a `SearchIndex` action method to the existing `MoviesController` class. The method will return a view that contains an HTML form. Here's the code:

```
public ActionResult SearchIndex(string searchString)
{
    var movies = from m in db.Movies
                 select m;

    if (!String.IsNullOrEmpty(searchString))
    {
        movies = movies.Where(s => s.Title.Contains(searchString));
    }

    return View(movies);
}
```

The first line of the `SearchIndex` method creates the following LINQ query to select the movies:

```
var movies = from m in db.Movies
             select m;
```

The query is defined at this point, but hasn't yet been run against the data store.

If the `searchString` parameter contains a string, the movies query is modified to filter on the value of the search string, using the following code:

```
if (!String.IsNullOrEmpty(searchString))
{
    movies = movies.Where(s => s.Title.Contains(searchString));
}
```

LINQ queries are not executed when they are defined or when they are modified by calling a method such as `Where` or `OrderBy`. Instead, query execution is deferred, which means that the evaluation of an expression is delayed until its realized value is actually iterated over or the `ToList` method is called. In the `SearchIndex` sample, the query is executed in the SearchIndex view. For more information about deferred query execution, see Query Execution.

Now you can implement the `SearchIndex` view that will display the form to the user. Right-click inside the `SearchIndex` method and then click **Add View**. In the **Add View** dialog box, specify that you're going to pass a `Movie` object to the view template as its model class. In the **Scaffold template** list, choose **List**, then click **Add**.

When you click the **Add** button, the *Views\Movies\SearchIndex.cshtml* view template is created. Because you selected **List** in the **Scaffold template** list, Visual Web Developer automatically generated (scaffolded) some default content in the view. The scaffolding created an HTML form. It examined the `Movie` class and created code to render `<label>` elements for each property of the class. The listing below shows the Create view that was generated:

```
@model IEnumerable<MvcMovie.Models.Movie>

@{
    ViewBag.Title = "SearchIndex";
}

<h2>SearchIndex</h2>

<p>
    @Html.ActionLink("Create New", "Create")
</p>
<table>
    <tr>
        <th>
            Title
        </th>
        <th>
            ReleaseDate
        </th>
        <th>
            Genre
        </th>
        <th>
            Price
        </th>
        <th></th>
    </tr>

@foreach (var item in Model) {
    <tr>
        <td>
            @Html.DisplayFor(modelItem => item.Title)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.ReleaseDate)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Genre)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Price)
        </td>
        <td>
            @Html.ActionLink("Edit", "Edit", new { id=item.ID }) |
            @Html.ActionLink("Details", "Details", new { id=item.ID }) |
            @Html.ActionLink("Delete", "Delete", new { id=item.ID })
        </td>
    </tr>
}

</table>
```

Run the application and navigate to */Movies/SearchIndex*. Append a query string such as `?searchString=ghost` to the URL. The filtered movies are displayed.

If you change the signature of the `SearchIndex` method to have a parameter named `id`, the `id` parameter will match the `{id}` placeholder for the default routes set in the *Global.asax* file.

```
{controller}/{action}/{id}
```

The modified `SearchIndex` method would look as follows:

```
public ActionResult SearchIndex(string id)
{
    string searchString = id;
    var movies = from m in db.Movies
                 select m;

    if (!String.IsNullOrEmpty(searchString))
    {
        movies = movies.Where(s => s.Title.Contains(searchString));
    }

    return View(movies);
}
```

You can now pass the search title as route data (a URL segment) instead of as a query string value.

However, you can't expect users to modify the URL every time they want to search for a movie. So now you you'll add UI to help them filter movies. If you changed the signature of the `SearchIndex` method to test how to pass the route-bound ID parameter, change it back so that your `SearchIndex` method takes a string parameter named `searchString`:

```
public ActionResult SearchIndex(string searchString)
{
     var movies = from m in db.Movies
                  select m;

    if (!String.IsNullOrEmpty(searchString))
    {
        movies = movies.Where(s => s.Title.Contains(searchString));
    }

    return View(movies);
}
```

Open the *Views\Movies\SearchIndex.cshtml* file, and just after `@Html.ActionLink("Create New", "Create")`, add the following:

```
@using (Html.BeginForm()){
         <p> Title: @Html.TextBox("SearchString")
         <input type="submit" value="Filter" /></p>
        }
```

The following example shows a portion of the *Views\Movies\SearchIndex.cshtml* file with the added filtering markup.

```
@model IEnumerable<MvcMovie.Models.Movie>

@{
    ViewBag.Title = "SearchIndex";
}

<h2>SearchIndex</h2>

<p>
    @Html.ActionLink("Create New", "Create")

     @using (Html.BeginForm()){
         <p> Title: @Html.TextBox("SearchString") <br />
         <input type="submit" value="Filter" /></p>
        }
</p>
```

The `Html.BeginForm` helper creates an opening `<form>` tag. The `Html.BeginForm` helper causes the form to post to itself when the user submits the form by clicking the **Filter** button.

Run the application and try searching for a movie.

There's no `HttpPost` overload of the `SearchIndex` method. You don't need it, because the method isn't changing the state of the application, just filtering data.

You could add the following `HttpPost SearchIndex` method. In that case, the action invoker would match the `HttpPost SearchIndex` method, and the `HttpPost SearchIndex` method would run as shown in the image below.

```
[HttpPost]
public string SearchIndex(FormCollection fc, string searchString)
{
    return "<h3> From [HttpPost]SearchIndex: " + searchString + "</h3>";
}
```

However, even if you add this `HttpPost` version of the `SearchIndex` method, there's a limitation in how this has all been implemented. Imagine that you want to bookmark a particular search or you want to send a link to friends that they can click in order to see the same filtered list of movies. Notice that the URL for the HTTP POST request is the same as the URL for the GET request (localhost:xxxxx/Movies/SearchIndex) -- there's no search information in the URL itself. Right now, the search string information is sent to the server as a form field value. This means you can't capture that search information to bookmark or send to friends in a URL.

The solution is to use an overload of `BeginForm` that specifies that the POST request should add the search information to the URL and that is should be routed to the HttpGet version of the `SearchIndex` method. Replace the existing parameterless `BeginForm` method with the following:

```
@using (Html.BeginForm("SearchIndex","Movies",FormMethod.Get))
```

Now when you submit a search, the URL contains a search query string. Searching will also go to the `HttpGet SearchIndex` action method, even if you have a `HttpPost SearchIndex` method.

Adding Search by Genre

If you added the `HttpPost` version of the `SearchIndex` method, delete it now.

Next, you'll add a feature to let users search for movies by genre. Replace the `SearchIndex` method with the following code:

```
public ActionResult SearchIndex(string movieGenre, string searchString)
{
    var GenreLst = new List<string>();

    var GenreQry = from d in db.Movies
                   orderby d.Genre
                   select d.Genre;
    GenreLst.AddRange(GenreQry.Distinct());
    ViewBag.movieGenre = new SelectList(GenreLst);

    var movies = from m in db.Movies
                 select m;

    if (!String.IsNullOrEmpty(searchString))
    {
        movies = movies.Where(s => s.Title.Contains(searchString));
    }

    if (string.IsNullOrEmpty(movieGenre))
        return View(movies);
    else
    {
        return View(movies.Where(x => x.Genre == movieGenre));
    }
}
```

This version of the `SearchIndex` method takes an additional parameter, namely `movieGenre`. The first few lines of

code create a `List` object to hold movie genres from the database.

The following code is a LINQ query that retrieves all the genres from the database.

```
var GenreQry = from d in db.Movies
               orderby d.Genre
               select d.Genre;
```

The code uses the `AddRange` method of the generic `List` collection to add all the distinct genres to the list. (Without the `Distinct` modifier, duplicate genres would be added — for example, comedy would be added twice in our sample). The code then stores the list of genres in the `ViewBag` object.

The following code shows how to check the `movieGenre` parameter. If it's not empty the code further constrains the movies query to limit the selected movies to the specified genre.

```
if (string.IsNullOrEmpty(movieGenre))
        return View(movies);
else
{
    return View(movies.Where(x => x.Genre == movieGenre));
}
```

Adding Markup to the SearchIndex View to Support Search by Genre

Add an `Html.DropDownList` helper to the *Views\Movies\SearchIndex.cshtml* file, just before the `TextBox` helper. The completed markup is shown below:

```
<p>
    @Html.ActionLink("Create New", "Create")
    @using (Html.BeginForm()){
         <p>Genre: @Html.DropDownList("movieGenre", "All")
           Title: @Html.TextBox("SearchString")
         <input type="submit" value="Filter" /></p>
        }
</p>
```

Run the application and browse to */Movies/SearchIndex*. Try a search by genre, by movie name, and by both criteria.

In this section you examined the CRUD action methods and views generated by the framework. You created a search action method and view that let users search by movie title and genre. In the next section, you'll look at how to add a property to the `Movie` model and how to add an initializer that will automatically create a test database.

Adding a New Field to the Movie Model and Table (C#)

2/20/2020 • 7 minutes to read • Edit Online

by Rick Anderson

> **NOTE**
>
> An updated version of this tutorial is available here that uses ASP.NET MVC 5 and Visual Studio 2013. It's more secure, much simpler to follow and demonstrates more features.

This tutorial will teach you the basics of building an ASP.NET MVC Web application using Microsoft Visual Web Developer 2010 Express Service Pack 1, which is a free version of Microsoft Visual Studio. Before you start, make sure you've installed the prerequisites listed below. You can install all of them by clicking the following link: Web Platform Installer. Alternatively, you can individually install the prerequisites using the following links:

- Visual Studio Web Developer Express SP1 prerequisites
- ASP.NET MVC 3 Tools Update
- SQL Server Compact 4.0(runtime + tools support)

If you're using Visual Studio 2010 instead of Visual Web Developer 2010, install the prerequisites by clicking the following link: Visual Studio 2010 prerequisites.

A Visual Web Developer project with C# source code is available to accompany this topic. Download the C# version. If you prefer Visual Basic, switch to the Visual Basic version of this tutorial.

In this section you'll make some changes to the model classes and learn how you can update the database schema to match the model changes.

Adding a Rating Property to the Movie Model

Start by adding a new `Rating` property to the existing `Movie` class. Open the *Movie.cs* file and add the `Rating` property like this one:

```
public string Rating { get; set; }
```

The complete `Movie` class now looks like the following code:

```
public class Movie
{
    public int      ID          { get; set; }
    public string   Title       { get; set; }
    public DateTime ReleaseDate { get; set; }
    public string   Genre       { get; set; }
    public decimal  Price       { get; set; }
    public string   Rating      { get; set; }
}
```

Recompile the application using the **Debug** >**Build Movie** menu command.

Now that you've updated the `Model` class, you also need to update the *\Views\Movies\Index.cshtml* and *\Views\Movies\Create.cshtml* view templates in order to support the new `Rating` property.

Open the *\Views\Movies\Index.cshtml* file and add a `<th>Rating</th>` column heading just after the **Price** column. Then add a `<td>` column near the end of the template to render the `@item.Rating` value. Below is what the updated *Index.cshtml* view template looks like:

```
<table>
    <tr>
        <th></th>
        <th>Title</th>
        <th>Release Date</th>
        <th>Genre</th>
        <th>Price</th>
        <th>Rating</th>
    </tr>

@foreach (var item in Model) {
    <tr>
        <td>
            @Html.DisplayFor(modelItem => item.Title)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.ReleaseDate)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Genre)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Price)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Rating   )
        </td>
        <td>
            @Html.ActionLink("Edit Me", "Edit", new { id=item.ID }) |
            @Html.ActionLink("Details", "Details", new { id=item.ID }) |
            @Html.ActionLink("Delete", "Delete", new { id=item.ID })
        </td>
    </tr>
}
</table>
```

Next, open the *\Views\Movies\Create.cshtml* file and add the following markup near the end of the form. This renders a text box so that you can specify a rating when a new movie is created.

```
<div class="editor-label">
    @Html.LabelFor(model => model.Rating)
</div>
<div class="editor-field">
    @Html.EditorFor(model => model.Rating)
    @Html.ValidationMessageFor(model => model.Rating)
</div>
```

Managing Model and Database Schema Differences

You've now updated the application code to support the new `Rating` property.

Now run the application and navigate to the */Movies* URL. When you do this, though, you'll see the following error:

You're seeing this error because the updated `Movie` model class in the application is now different than the schema of the `Movie` table of the existing database. (There's no `Rating` column in the database table.)

By default, when you use Entity Framework Code First to automatically create a database, as you did earlier in this tutorial, Code First adds a table to the database to help track whether the schema of the database is in sync with the model classes it was generated from. If they aren't in sync, the Entity Framework throws an error. This makes it easier to track down issues at development time that you might otherwise only find (by obscure errors) at run time. The sync-checking feature is what causes the error message to be displayed that you just saw.

There are two approaches to resolving the error:

1. Have the Entity Framework automatically drop and re-create the database based on the new model class schema. This approach is very convenient when doing active development on a test database, because it allows you to quickly evolve the model and database schema together. The downside, though, is that you lose existing data in the database — so you *don't* want to use this approach on a production database!
2. Explicitly modify the schema of the existing database so that it matches the model classes. The advantage of this approach is that you keep your data. You can make this change either manually or by creating a database change script.

For this tutorial, we'll use the first approach — you'll have the Entity Framework Code First automatically re-create the database anytime the model changes.

Automatically Re-Creating the Database on Model Changes

Let's update the application so that Code First automatically drops and re-creates the database anytime you

change the model for the application.

> **NOTE**
>
> **Warning** You should enable this approach of automatically dropping and re-creating the database only when you're using a development or test database, and *never* on a production database that contains real data. Using it on a production server can lead to data loss.

In **Solution Explorer**, right click the *Models* folder, select **Add**, and then select **Class**.

Name the class "MovieInitializer". Update the `MovieInitializer` class to contain the following code:

```
using System;
using System.Collections.Generic;
using System.Data.Entity;

namespace MvcMovie.Models {
    public class MovieInitializer : DropCreateDatabaseIfModelChanges<MovieDBContext> {
        protected override void Seed(MovieDBContext context) {
            var movies = new List<Movie> {

                 new Movie { Title = "When Harry Met Sally",
                             ReleaseDate=DateTime.Parse("1989-1-11"),
                             Genre="Romantic Comedy",
                             Rating="R",
                             Price=7.99M},

                     new Movie { Title = "Ghostbusters ",
                             ReleaseDate=DateTime.Parse("1984-3-13"),
                             Genre="Comedy",
                              Rating="R",
                             Price=8.99M},

                 new Movie { Title = "Ghostbusters 2",
                             ReleaseDate=DateTime.Parse("1986-2-23"),
                             Genre="Comedy",
                             Rating="R",
                             Price=9.99M},

               new Movie { Title = "Rio Bravo",
                             ReleaseDate=DateTime.Parse("1959-4-15"),
                             Genre="Western",
                             Rating="R",
                             Price=3.99M},
             };

            movies.ForEach(d => context.Movies.Add(d));
        }
    }
}
```

The `MovieInitializer` class specifies that the database used by the model should be dropped and automatically re-created if the model classes ever change. The code includes a `Seed` method to specify some default data to automatically add to the database any time it's created (or re-created). This provides a useful way to populate the database with some sample data, without requiring you to manually populate it each time you make a model change.

Now that you've defined the `MovieInitializer` class, you'll want to wire it up so that each time the application runs, it checks whether the model classes are different from the schema in the database. If they are, you can run the initializer to re-create the database to match the model and then populate the database with the sample data.

Open the *Global.asax* file that's at the root of the `MvcMovies` project:

The *Global.asax* file contains the class that defines the entire application for the project, and contains an `Application_Start` event handler that runs when the application first starts.

Let's add two using statements to the top of the file. The first references the Entity Framework namespace, and the second references the namespace where our `MovieInitializer` class lives:

```
using System.Data.Entity;            // Database.SetInitialize
using MvcMovie.Models;              // MovieInitializer
```

Then find the `Application_Start` method and add a call to `Database.SetInitializer` at the beginning of the method, as shown below:

```
protected void Application_Start()
{
    Database.SetInitializer<MovieDBContext>(new MovieInitializer());

    AreaRegistration.RegisterAllAreas();
    RegisterGlobalFilters(GlobalFilters.Filters);
    RegisterRoutes(RouteTable.Routes);
}
```

The `Database.SetInitializer` statement you just added indicates that the database used by the `MovieDBContext` instance should be automatically deleted and re-created if the schema and the database don't match. And as you saw, it will also populate the database with the sample data that's specified in the `MovieInitializer` class.

Close the *Global.asax* file.

Re-run the application and navigate to the */Movies* URL. When the application starts, it detects that the model structure no longer matches the database schema. It automatically re-creates the database to match the new model structure and populates the database with the sample movies:

Click the **Create New** link to add a new movie. Note that you can add a rating.

Click **Create**. The new movie, including the rating, now shows up in the movies listing:

In this section you saw how you can modify model objects and keep the database in sync with the changes. You also learned a way to populate a newly created database with sample data so you can try out scenarios. Next, let's look at how you can add richer validation logic to the model classes and enable some business rules to be enforced.

Adding Validation to the Model (C#)

2/20/2020 • 8 minutes to read • Edit Online

by Rick Anderson

> **NOTE**
> An updated version of this tutorial is available here that uses ASP.NET MVC 5 and Visual Studio 2013. It's more secure, much simpler to follow and demonstrates more features.

This tutorial will teach you the basics of building an ASP.NET MVC Web application using Microsoft Visual Web Developer 2010 Express Service Pack 1, which is a free version of Microsoft Visual Studio. Before you start, make sure you've installed the prerequisites listed below. You can install all of them by clicking the following link: Web Platform Installer. Alternatively, you can individually install the prerequisites using the following links:

- Visual Studio Web Developer Express SP1 prerequisites
- ASP.NET MVC 3 Tools Update
- SQL Server Compact 4.0(runtime + tools support)

If you're using Visual Studio 2010 instead of Visual Web Developer 2010, install the prerequisites by clicking the following link: Visual Studio 2010 prerequisites.

A Visual Web Developer project with C# source code is available to accompany this topic. Download the C# version. If you prefer Visual Basic, switch to the Visual Basic version of this tutorial.

In this section you'll add validation logic to the `Movie` model, and you'll ensure that the validation rules are enforced any time a user attempts to create or edit a movie using the application.

Keeping Things DRY

One of the core design tenets of ASP.NET MVC is DRY ("Don't Repeat Yourself"). ASP.NET MVC encourages you to specify functionality or behavior only once, and then have it be reflected everywhere in an application. This reduces the amount of code you need to write and makes the code you do write much easier to maintain.

The validation support provided by ASP.NET MVC and Entity Framework Code First is a great example of the DRY principle in action. You can declaratively specify validation rules in one place (in the model class) and then those rules are enforced everywhere in the application.

Let's look at how you can take advantage of this validation support in the movie application.

Adding Validation Rules to the Movie Model

You'll begin by adding some validation logic to the `Movie` class.

Open the *Movie.cs* file. Add a `using` statement at the top of the file that references the `System.ComponentModel.DataAnnotations` namespace:

```
using System.ComponentModel.DataAnnotations;
```

The namespace is part of the .NET Framework. It provides a built-in set of validation attributes that you can apply declaratively to any class or property.

Now update the `Movie` class to take advantage of the built-in `Required`, `StringLength`, and `Range` validation attributes. Use the following code as an example of where to apply the attributes.

```
public class Movie
{
    public int ID { get; set; }

    [Required(ErrorMessage = "Title is required")]
    public string Title { get; set; }

    [Required(ErrorMessage = "Date is required")]
    public DateTime ReleaseDate { get; set; }

    [Required(ErrorMessage = "Genre must be specified")]
    public string Genre { get; set; }

    [Range(1, 100, ErrorMessage = "Price must be between $1 and $100")]
    public decimal Price { get; set; }

    [StringLength(5)]
    public string Rating { get; set; }
}
```

The validation attributes specify behavior that you want to enforce on the model properties they are applied to. The `Required` attribute indicates that a property must have a value; in this sample, a movie has to have values for the `Title`, `ReleaseDate`, `Genre`, and `Price` properties in order to be valid. The `Range` attribute constrains a value to within a specified range. The `StringLength` attribute lets you set the maximum length of a string property, and optionally its minimum length.

Code First ensures that the validation rules you specify on a model class are enforced before the application saves changes in the database. For example, the code below will throw an exception when the `SaveChanges` method is called, because several required `Movie` property values are missing and the price is zero (which is out of the valid range).

```
MovieDBContext db = new MovieDBContext();

Movie movie = new Movie();
movie.Title = "Gone with the Wind";
movie.Price = 0.0M;

db.Movies.Add(movie);
db.SaveChanges();        // <= Will throw validation exception
```

Having validation rules automatically enforced by the .NET Framework helps make your application more robust. It also ensures that you can't forget to validate something and inadvertently let bad data into the database.

Here's a complete code listing for the updated *Movie.cs* file:

```
using System;
using System.Data.Entity;
using System.ComponentModel.DataAnnotations;

namespace MvcMovie.Models
{
    public class Movie
    {
        public int ID { get; set; }

        [Required(ErrorMessage = "Title is required")]
        public string Title { get; set; }

        public DateTime ReleaseDate { get; set; }

        [Required(ErrorMessage = "Genre must be specified")]
        public string Genre { get; set; }

        [Range(1, 100, ErrorMessage = "Price must be between $1 and $100")]
        public decimal Price { get; set; }

        [StringLength(5)]
        public string Rating { get; set; }
    }

    public class MovieDBContext : DbContext
    {
        public DbSet<Movie> Movies { get; set; }
    }
}
```

Validation Error UI in ASP.NET MVC

Re-run the application and navigate to the */Movies* URL.

Click the **Create Movie** link to add a new movie. Fill out the form with some invalid values and then click the **Create** button.

Notice how the form has automatically used a background color to highlight the text boxes that contain invalid data and has emitted an appropriate validation error message next to each one. The error messages match the error strings you specified when you annotated the `Movie` class. The errors are enforced both client-side (using JavaScript) and server-side (in case a user has JavaScript disabled).

A real benefit is that you didn't need to change a single line of code in the `MoviesController` class or in the *Create.cshtml* view in order to enable this validation UI. The controller and views you created earlier in this tutorial automatically picked up the validation rules that you specified using attributes on the `Movie` model class.

How Validation Occurs in the Create View and Create Action Method

You might wonder how the validation UI was generated without any updates to the code in the controller or views. The next listing shows what the `Create` methods in the `MovieController` class look like. They're unchanged from how you created them earlier in this tutorial.

```
//
// GET: /Movies/Create

public ActionResult Create()
{
    return View();
}

//
// POST: /Movies/Create

[HttpPost]
public ActionResult Create(Movie movie)
{
    if (ModelState.IsValid)
    {
        db.Movies.Add(movie);
        db.SaveChanges();
        return RedirectToAction("Index");
    }

    return View(movie);
}
```

The first action method displays the initial Create form. The second handles the form post. The second `Create` method calls `ModelState.IsValid` to check whether the movie has any validation errors. Calling this method evaluates any validation attributes that have been applied to the object. If the object has validation errors, the `Create` method redisplays the form. If there are no errors, the method saves the new movie in the database.

Below is the *Create.cshtml* view template that you scaffolded earlier in the tutorial. It's used by the action methods shown above both to display the initial form and to redisplay it in the event of an error.

```
@model MvcMovie.Models.Movie
@{
    ViewBag.Title = "Create";
}
<h2>
    Create</h2>
<script src="@Url.Content("~/Scripts/jquery.validate.min.js")" type="text/javascript"></script>
<script src="@Url.Content("~/Scripts/jquery.validate.unobtrusive.min.js")" type="text/javascript"></script>
@using (Html.BeginForm())
{
    @Html.ValidationSummary(true)
    <fieldset>
        <legend>Movie</legend>
        <div class="editor-label">
            @Html.LabelFor(model => model.Title)
        </div>
        <div class="editor-field">
            @Html.EditorFor(model => model.Title)
            @Html.ValidationMessageFor(model => model.Title)
        </div>
        <div class="editor-label">
            @Html.LabelFor(model => model.ReleaseDate)
        </div>
        <div class="editor-field">
            @Html.EditorFor(model => model.ReleaseDate)
            @Html.ValidationMessageFor(model => model.ReleaseDate)
        </div>
        <div class="editor-label">
            @Html.LabelFor(model => model.Genre)
        </div>
        <div class="editor-field">
            @Html.EditorFor(model => model.Genre)
            @Html.ValidationMessageFor(model => model.Genre)
        </div>
        <div class="editor-label">
            @Html.LabelFor(model => model.Price)
        </div>
        <div class="editor-field">
            @Html.EditorFor(model => model.Price)
            @Html.ValidationMessageFor(model => model.Price)
        </div>
        <div class="editor-label">
            @Html.LabelFor(model => model.Rating)
        </div>
        <div class="editor-field">
            @Html.EditorFor(model => model.Rating)
            @Html.ValidationMessageFor(model => model.Rating)
        </div>
        <p>
            <input type="submit" value="Create" />
        </p>
    </fieldset>
}
<div>
    @Html.ActionLink("Back to List", "Index")
</div>
```

Notice how the code uses an `Html.EditorFor` helper to output the `<input>` element for each `Movie` property. Next to this helper is a call to the `Html.ValidationMessageFor` helper method. These two helper methods work with the model object that's passed by the controller to the view (in this case, a `Movie` object). They automatically look for validation attributes specified on the model and display error messages as appropriate.

What's really nice about this approach is that neither the controller nor the Create view template knows anything about the actual validation rules being enforced or about the specific error messages displayed. The validation

rules and the error strings are specified only in the `Movie` class.

If you want to change the validation logic later, you can do so in exactly one place. You won't have to worry about different parts of the application being inconsistent with how the rules are enforced — all validation logic will be defined in one place and used everywhere. This keeps the code very clean, and makes it easy to maintain and evolve. And it means that you'll be fully honoring the DRY principle.

Adding Formatting to the Movie Model

Open the *Movie.cs* file. The `System.ComponentModel.DataAnnotations` namespace provides formatting attributes in addition to the built-in set of validation attributes. You'll apply the `DisplayFormat` attribute and a `DataType` enumeration value to the release date and to the price fields. The following code shows the `ReleaseDate` and `Price` properties with the appropriate `DisplayFormat` attribute.

```
[DataType(DataType.Date)]
public DateTime ReleaseDate { get; set; }

[DataType(DataType.Currency)]
public decimal Price { get; set; }
```

Alternatively, you could explicitly set a `DataFormatString` value. The following code shows the release date property with a date format string (namely, "d"). You'd use this to specify that you don't want to time as part of the release date.

```
[DisplayFormat(DataFormatString = "{0:d}")]
public DateTime ReleaseDate { get; set; }
```

The following code formats the `Price` property as currency.

```
[DisplayFormat(DataFormatString = "{0:c}")]
public decimal Price { get; set; }
```

The complete `Movie` class is shown below.

```
public class Movie
{
    public int ID { get; set; }

    [Required(ErrorMessage = "Title is required")]
    public string Title { get; set; }

    [DisplayFormat(DataFormatString = "{0:d}")]
    public DateTime ReleaseDate { get; set; }

    [Required(ErrorMessage = "Genre must be specified")]
    public string Genre { get; set; }

    [Range(1, 100, ErrorMessage = "Price must be between $1 and $100")]
    [DisplayFormat(DataFormatString = "{0:c}")]
    public decimal Price { get; set; }

    [StringLength(5)]
    public string Rating { get; set; }
}
```

Run the application and browse to the `Movies` controller.

In the next part of the series, we'll review the application and make some improvements to the automatically generated `Details` and `Delete` methods.

Improving the Details and Delete Methods (C#)

2/20/2020 • 5 minutes to read • Edit Online

by Rick Anderson

> **NOTE**
>
> An updated version of this tutorial is available here that uses ASP.NET MVC 5 and Visual Studio 2013. It's more secure, much simpler to follow and demonstrates more features.

This tutorial will teach you the basics of building an ASP.NET MVC Web application using Microsoft Visual Web Developer 2010 Express Service Pack 1, which is a free version of Microsoft Visual Studio. Before you start, make sure you've installed the prerequisites listed below. You can install all of them by clicking the following link: Web Platform Installer. Alternatively, you can individually install the prerequisites using the following links:

- Visual Studio Web Developer Express SP1 prerequisites
- ASP.NET MVC 3 Tools Update
- SQL Server Compact 4.0(runtime + tools support)

If you're using Visual Studio 2010 instead of Visual Web Developer 2010, install the prerequisites by clicking the following link: Visual Studio 2010 prerequisites.

A Visual Web Developer project with C# source code is available to accompany this topic. Download the C# version. If you prefer Visual Basic, switch to the Visual Basic version of this tutorial.

In this part of the tutorial, you'll make some improvements to the automatically generated `Details` and `Delete` methods. These changes aren't required, but with just a few small bits of code, you can easily enhance the application.

Improving the Details and Delete Methods

When you scaffolded the `Movie` controller, ASP.NET MVC generated code that worked great, but that can be made more robust with just a few small changes.

Open the `Movie` controller and modify the `Details` method by returning `HttpNotFound` when a movie isn't found. You should also modify the `Details` method to set a default value for the ID that's passed to it. (You made similar changes to the `Edit` method in part 6 of this tutorial.) However, you must change the return type of the `Details` method from `ViewResult` to `ActionResult`, because the `HttpNotFound` method doesn't return a `ViewResult` object. The following example shows the modified `Details` method.

```
public ActionResult Details(int id = 0)
{
    Movie movie = db.Movies.Find(id);
    if (movie == null)
    {
        return HttpNotFound();
    }
    return View(movie);
}
```

Code First makes it easy to search for data using the `Find` method. An important security feature that we built into the method is that the code verifies that the `Find` method has found a movie before the code tries to do anything with it. For example, a hacker could introduce errors into the site by changing the URL created by the links from `http://localhost:xxxx/Movies/Details/1` to something like `http://localhost:xxxx/Movies/Details/12345` (or some other value that doesn't represent an actual movie). If you don't the check for a null movie, this could result in a database error.

Similarly, change the `Delete` and `DeleteConfirmed` methods to specify a default value for the ID parameter and to return `HttpNotFound` when a movie isn't found. The updated `Delete` methods in the `Movie` controller are shown below.

```
// GET: /Movies/Delete/5

public ActionResult Delete(int id = 0)
{
    Movie movie = db.Movies.Find(id);
    if (movie == null)
    {
        return HttpNotFound();
    }
    return View(movie);
}

//
// POST: /Movies/Delete/5

[HttpPost, ActionName("Delete")]
public ActionResult DeleteConfirmed(int id = 0)
{
    Movie movie = db.Movies.Find(id);
    if (movie == null)
    {
        return HttpNotFound();
    }
    db.Movies.Remove(movie);
    db.SaveChanges();
    return RedirectToAction("Index");
}
```

Note that the `Delete` method doesn't delete the data. Performing a delete operation in response to a GET request (or for that matter, performing an edit operation, create operation, or any other operation that changes data) opens up a security hole. For more information about this, see Stephen Walther's blog entry ASP.NET MVC Tip #46 — Don't use Delete Links because they create Security Holes.

The `HttpPost` method that deletes the data is named `DeleteConfirmed` to give the HTTP POST method a unique signature or name. The two method signatures are shown below:

```
// GET: /Movies/Delete/5
public ActionResult Delete(int id = 0)

//
// POST: /Movies/Delete/5
[HttpPost, ActionName("Delete")]
public ActionResult DeleteConfirmed(int id = 0)
```

The common language runtime (CLR) requires overloaded methods to have a unique signature (same name, different list of parameters). However, here you need two Delete methods -- one for GET and one for POST -- that both require the same signature. (They both need to accept a single integer as a parameter.)

To sort this out, you can do a couple of things. One is to give the methods different names. That's what we did in

he preceding example. However, this introduces a small problem: ASP.NET maps segments of a URL to action methods by name, and if you rename a method, routing normally wouldn't be able to find that method. The solution is what you see in the example, which is to add the `ActionName("Delete")` attribute to the `DeleteConfirmed` method. This effectively performs mapping for the routing system so that a URL that includes */Delete/* for a POST request will find the `DeleteConfirmed` method.

Another way to avoid a problem with methods that have identical names and signatures is to artificially change the signature of the POST method to include an unused parameter. For example, some developers add a parameter type `FormCollection` that is passed to the POST method, and then simply don't use the parameter:

```
public ActionResult Delete(FormCollection fcNotUsed, int id = 0)
{
    Movie movie = db.Movies.Find(id);
    if (movie == null)
    {
        return HttpNotFound();
    }
    db.Movies.Remove(movie);
    db.SaveChanges();
    return RedirectToAction("Index");
}
```

Wrapping Up

You now have a complete ASP.NET MVC application that stores data in a SQL Server Compact database. You can create, read, update, delete, and search for movies.

This basic tutorial got you started making controllers, associating them with views, and passing around hard-coded data. Then you created and designed a data model. Entity Framework Code First created a database from the data model on the fly, and the ASP.NET MVC scaffolding system automatically generated the action methods and views for basic CRUD operations. You then added a search form that let users search the database. You

changed the database to include a new column of data, and then updated two pages to create and display this new data. You added validation by marking the data model with attributes from the `DataAnnotations` namespace. The resulting validation runs on the client and on the server.

If you'd like to deploy your application, it's helpful to first test the application on your local IIS 7 server. You can use this Web Platform Installer link to enable IIS setting for ASP.NET applications. See the following deployment links:

- ASP.NET Deployment Content Map
- Enabling IIS 7.x
- Web Application Projects Deployment

I now encourage you to move on to our intermediate-level Creating an Entity Framework Data Model for an ASP.NET MVC Application and MVC Music Store tutorials, to explore the ASP.NET articles on MSDN, and to check out the many videos and resources at https://asp.net/mvc to learn even more about ASP.NET MVC! The ASP.NET MVC forums are a great place to ask questions.

Enjoy!

A Visual Web Developer project with VB source code is available to accompany this topic. Download the VB version here. If you prefer CSharp, switch to the CSharp version of this tutorial.

What You'll Build

You'll implement a simple movie-listing application that supports creating, editing, and listing movies from a database. Below are two screenshots of the application you'll build. It includes a page that displays a list of movies from a database:

The application also lets you add, edit, and delete movies, as well as see details about individual ones. All data-entry scenarios include validation to ensure that the data stored in the database is correct.

Skills You'll Learn

Here's what you'll learn:

- How to create a new ASP.NET MVC project
- How to create a new database using Entity Framework code-first
- How to create ASP.NET MVC controllers and views
- How to retrieve and display data
- How to edit data and enable data validation

Getting Started

Start by running Visual Web Developer 2010 Express ("VWD" for short) and select **New Project** from the **Start** page.

Visual Web Developer is an IDE, or integrated development environment. Just like you use Microsoft Word to write documents, you'll use an IDE to create applications. In Visual Web Developer there's a toolbar along the top showing various options available to you. There's also a menu that provides another way to perform tasks in the IDE. (For example, instead of selecting **New Project** from the **Start** page, you can use the menu and select **File** > **New Project**.)

Creating Your First Application

You can create applications using your choice of either Visual Basic or Visual C# as the programming language. For this tutorial, select Visual Basic on the left, then select **ASP.NET MVC 3 Web Application**. Name your project "MvcMovie" and then click **OK**.

In the **New ASP.NET MVC 3 Project** dialog box, select **Internet Application**. Leave **Razor** as the default view engine.

Click **OK**. Visual Web Developer used a default template for the ASP.NET MVC project you just created, so you have a working application right now without doing anything! This is a simple "Hello World!" project, and it's a good place to start your application.

From the **Debug** menu, select **Start Debugging**.

Notice that the keyboard shortcut to start debugging is F5.

F5 causes Visual Web Developer to start a development web server and run your web application. VWD then launches a browser and opens the application's home page. Notice that the address bar of the browser says `localhost` and not something like `example.com`. That's because `localhost` always points to your own local computer, which in this case is running the application you just built. When VWD runs a web project, a random port is used for the project. In the image below, the random port number is 43246. Your project will probably use a different port number.

Out of the box this default template gives you two pages to visit and a basic login page. Let's change how this application works and learn a little bit about ASP.NET MVC in the process. Close your browser and let's change some code.

A Visual Web Developer project with VB.NET source code is available to accompany this topic. Download the VB.NET version. If you prefer C#, switch to the C# version of this tutorial.

MVC stands for *model-view-controller*. MVC is a pattern for developing applications such that each part has a separate responsibility:

- Model: The data for your application.
- Views: The template files your application will use to dynamically generate HTML responses.
- Controllers: Classes that handle incoming URL requests to the application, retrieve model data, and then specify view templates that render a response to the client.

We'll be covering all these concepts in this tutorial and show you how to use them to build an application.

Create a new controller by right-clicking the *Controllers* folder in **Solution Explorer** and then selecting **Add Controller**.

Name your new controller "HelloWorldController" and click **Add**.

Notice in **Solution Explorer** on the right that a new file has been created for you named *HelloWorldController.cs* and that the file is open in the IDE.

Inside the new `public class HelloWorldController` block, create two new methods that look like the following code. We'll return a string of HTML directly from the controller as an example.

```
Namespace MvcMovie
    Public Class HelloWorldController
        Inherits System.Web.Mvc.Controller

        Public Function Index() As String
            Return "This is my default action..."
        End Function

        Public Function Welcome() As String
            Return "This is the Welcome action method..."
        End Function

    End Class
End Namespace
```

Your controller is named `HelloWorldController` and your new method is named `Index`. Run the application (press F5 or Ctrl+F5). Once your browser has started up, append "HelloWorld" to the path in the address bar. (On my computer, it's `http://localhost:43246/HelloWorld`) Your browser will look like the screenshot below. In the method above, the code returned a string directly. We told the system to just return some HTML, and it did!

ASP.NET MVC invokes different controller classes (and different action methods within them) depending on the incoming URL. The default mapping logic used by ASP.NET MVC uses a format like this to control what code is invoked:

```
/[Controller]/[ActionName]/[Parameters]
```

The first part of the URL determines the controller class to execute. So */HelloWorld* maps to the `HelloWorldController` class. The second part of the URL determines the action method on the class to execute. So */HelloWorld/Index* would cause the `Index` method of the `HelloWorldController` class to execute. Notice that we only had to visit */HelloWorld* above and the `Index` method was used by default. This is because a method named `Index` is the default method that will be called on a controller if one is not explicitly specified.

Browse to `http://localhost:xxxx/HelloWorld/Welcome`. The `Welcome` method runs and returns the string "This is the Welcome action method...". The default MVC mapping is `/[Controller]/[ActionName]/[Parameters]`. For this URL, the controller is `HelloWorld` and `Welcome` is the method. We haven't used the `[Parameters]` part of the URL yet.

Let's modify the example slightly so that we can pass some parameter information in from the URL to the

controller (for example, */HelloWorld/Welcome?name=Scott&numtimes=4*). Change your `Welcome` method to include two parameters as shown below. Note that we've used the VB optional parameter feature to indicate that the `numTimes` parameter should default to 1 if no value is passed for that parameter.

```
Public Function Welcome(ByVal name As String, Optional ByVal numTimes As Integer = 1) As String
    Dim message As String = "Hello " & name & ", NumTimes is: " & numTimes
    Return "" & Server.HtmlEncode(message) & ""
End Function
```

Run your application and browse to `http://localhost:xxxx/HelloWorld/Welcome?name=Scott&numtimes=4`. You can try different values for `name` and `numtimes`. The system automatically maps the named parameters from your query string in the address bar to parameters in your method.

In both these examples the controller has been doing the VC portion of MVC — that is the view and controller work. The controller is returning HTML directly. Ordinarily we don't want controllers returning HTML directly, since that becomes very cumbersome to code. Instead we'll typically use a separate view template file to help generate the HTML response. Let's look at how we can do this.

Adding a View (VB)

2/20/2020 • 6 minutes to read • Edit Online

by Rick Anderson

This tutorial will teach you the basics of building an ASP.NET MVC Web application using Microsoft Visual Web Developer 2010 Express Service Pack 1, which is a free version of Microsoft Visual Studio. Before you start, make sure you've installed the prerequisites listed below. You can install all of them by clicking the following link: Web Platform Installer. Alternatively, you can individually install the prerequisites using the following links:

- Visual Studio Web Developer Express SP1 prerequisites
- ASP.NET MVC 3 Tools Update
- SQL Server Compact 4.0(runtime + tools support)

If you're using Visual Studio 2010 instead of Visual Web Developer 2010, install the prerequisites by clicking the following link: Visual Studio 2010 prerequisites.

A Visual Web Developer project with VB.NET source code is available to accompany this topic. Download the VB.NET version. If you prefer C#, switch to the C# version of this tutorial.

In this section we're going to modify the `HelloWorldController` class to use a view template file to cleanly encapsulate the process of generating HTML responses to a client.

Let's start by using a view template with the `Index` method in the `HelloWorldController` class. Currently the `Index` method returns a string with a message that is hard-coded within the controller class. Change the `Index` method to return a `View` object, as shown in the following:

```
Public Function Index() As ActionResult
            Return View()
        End Function
```

Let's now add a view template to our project that we can invoke with the `Index` method. To do this, right-click inside the `Index` method and click **Add View**.

The **Add View** dialog box appears. Leave the default entries and click the **Add** button.

The *MvcMovie\Views\HelloWorld* folder and the *MvcMovie\Views\HelloWorld\Index.vbhtml* file are created. You can see them in **Solution Explorer**:

Add some HTML under the `<h2>` tag. The modified *MvcMovie\Views\HelloWorld\Index.vbhtml* file is shown below.

```
@Code
    ViewData("Title") = "Index"
End Code

<h2>Index</h2>

<b>Hello</b> World!
```

Run the application and browse to the "hello world" controller (`http://localhost:xxxx/HelloWorld`). The `Index` method in your controller didn't do much work; it simply ran the statement `return View()`, which indicated that we wanted to use a view template file to render a response to the client. Because we did not explicitly specify the name of the view template file to use, ASP.NET MVC defaulted to using the *Index.vbhtml* view file within the *\Views\HelloWorld* folder. The image below shows the string hard-coded in the view.

Looks pretty good. However, notice that the browser's title bar says "Index" and the big title on the page says "My MVC Application." Let's change those.

Changing views and layout pages

First, let's change the text "My MVC Application." That text is shared and appears on every page. It actually appears in only one place in our project, even though it's on every page in our application. Go to the */Views/Shared* folder in **Solution Explorer** and open the *_Layout.vbhtml* file. This file is called a layout page and it's the shared "shell" that all other pages use.

Note the `@RenderBody()` line of code near the bottom of the file. `RenderBody` is a placeholder where all the pages you create show up, "wrapped" in the layout page. Change the `<h1>` heading from " My MVC Application" to "MVC Movie App".

```
<div id="title">
        <h1>MVC Movie App</h1>
  </div>
```

Run the application and note it now says "MVC Movie App". Click the **About** link, and that page shows "MVC Movie App", too.

The complete *_Layout.vbhtml* file is shown below:

```
<!DOCTYPE html>
<html>
<head>
    <meta charset="utf-8" />
    <title>@ViewData("Title")</title>
    <link href="@Url.Content("~/Content/Site.css")" rel="stylesheet" type="text/css" />
    <script src="@Url.Content("~/Scripts/jquery-1.5.1.min.js")" type="text/javascript"></script>
    <script src="@Url.Content("~/Scripts/modernizr-1.7.min.js")" type="text/javascript"></script>
</head>
<body>
    <div class="page">
        <header>
            <div id="title">
                <h1>MVC Movie App</h1>
            </div>
            <div id="logindisplay">
                @Html.Partial("_LogOnPartial")
            </div>
            <nav>
                <ul id="menu">
                    <li>@Html.ActionLink("Home", "Index", "HelloWorld")</li>
                    <li>@Html.ActionLink("About", "About", "Home")</li>
                </ul>
            </nav>
        </header>
        <section id="main">
            @RenderBody()
        </section>
        <footer>
        </footer>
    </div>
</body>
</html>
```

Now, let's change the title of the Index page (view).

```
@Code
    ViewData("Title") = "Movie List"
End Code

<h2>My Movie List</h2>

<p>Hello from our View Template!</p>
```

Open *MvcMovie\Views\HelloWorld\Index.vbhtml*. There are two places to make a change: first, the text that appears in the title of the browser, and then in the secondary header (the `<h2>` element). We'll make them slightly different so you can see which bit of code changes which part of the app.

Run the application and browse to `http://localhost:xx/HelloWorld`. Notice that the browser title, the primary heading, and the secondary headings have changed. It's easy to make big changes in your application with small changes to a view. (If you don't see changes in the browser, you might be viewing cached content. Press Ctrl+F5 in your browser to force the response from the server to be loaded.)

Our little bit of "data" (in this case the "Hello World!" message) is hard-coded, though. Our MVC application has V (views) and we've got C (controllers), but no M (model) yet. Shortly, we'll walk through how create a database and retrieve model data from it.

Passing Data from the Controller to the View

Before we go to a database and talk about models, though, let's first talk about passing information from the Controller to a View. We want to pass what a view template requires in order to render an HTML response to a client. These objects are typically created and passed by a controller class to a view template, and they should contain only the data that the view template requires — and no more.

Previously with the `HelloWorldController` class, the `Welcome` action method took a `name` and a `numTimes` parameter and then output the parameter values to the browser. Rather than have the controller continue to render this response directly, let's instead we'll put that data in a bag for the View. Controllers and Views can use a `ViewBag` object to hold that data. That will be passed over to a view template automatically, and used to render the HTML response using the contents of the bag as data. That way the controller is concerned with one thing and the view template with another — enabling us to maintain clean "separation of concerns" within the application.

Alternatively, we could define a custom class, then create an instance of that object on our own, fill it with data and pass it to the View. That is often called a ViewModel, because it's a custom Model for the View. For small amounts of data, however, the ViewBag works great.

Return to the *HelloWorldController.vb* file change the `Welcome` method inside the controller to put the Message and NumTimes into the ViewBag. The ViewBag is a dynamic object. That means you can put whatever you want in to it. The ViewBag has no defined properties until you put something inside it.

The complete `HelloWorldController.vb` with the new class in the same file.

```
Namespace MvcMovie
    Public Class HelloWorldController
        Inherits System.Web.Mvc.Controller
        '
        ' GET: /HelloWorld

        Function Index() As ActionResult
            Return View()
        End Function

        Public Function Welcome(ByVal name As String, Optional ByVal numTimes As Integer = 1) As ActionResult
            ViewBag.Message = "Hello " & name
            ViewBag.NumTimes = numTimes
            Return View()
        End Function

    End Class
End Namespace
```

Now our ViewBag contains data that will be passed over to the View automatically. Again, alternatively we could have passed in our own object like this if we liked:

```
return View(myCustomObject)
```

Now we need a `WelcomeView` template! Run the application so the new code is compiled. Close the browser, right-click inside the `Welcome` method, and then click **Add View**.

Here's what your **Add View** dialog box looks like.

Add the following code under the `<h2>` element in the new *Welcome*.vbhtml file. We'll make a loop and say "Hello" as many times as the user says we should!

```
@Code
    For i As Integer = 0 To ViewBag.NumTimes
@<h3> @ViewBag.Message @i.ToString </h3>
     Next i
 End Code
```

Run the application and browse to `http://localhost:xx/HelloWorld/Welcome?name=Scott&numtimes=4`

Now data is taken from the URL and passed to the controller automatically. The controller packages up the data into a `Model` object and passes that object to the view. The view than displays the data as HTML to the user.

Well, that was a kind of an "M" for model, but not the database kind. Let's take what we've learned and create a database of movies.

PREVIOUS NEXT

Adding a Model (VB)

2/20/2020 • 3 minutes to read • Edit Online

by Rick Anderson

This tutorial will teach you the basics of building an ASP.NET MVC Web application using Microsoft Visual Web Developer 2010 Express Service Pack 1, which is a free version of Microsoft Visual Studio. Before you start, make sure you've installed the prerequisites listed below. You can install all of them by clicking the following link: Web Platform Installer. Alternatively, you can individually install the prerequisites using the following links:

- Visual Studio Web Developer Express SP1 prerequisites
- ASP.NET MVC 3 Tools Update
- SQL Server Compact 4.0(runtime + tools support)

If you're using Visual Studio 2010 instead of Visual Web Developer 2010, install the prerequisites by clicking the following link: Visual Studio 2010 prerequisites.

A Visual Web Developer project with VB.NET source code is available to accompany this topic. Download the VB.NET version. If you prefer C#, switch to the C# version of this tutorial.

Adding a Model

In this section you'll add some classes for managing movies in a database. These classes will be the "model" part of the ASP.NET MVC application.

You'll use a .NET Framework data-access technology known as the Entity Framework to define and work with these model classes. The Entity Framework (often referred to as EF) supports a development paradigm called *Code First*. Code First allows you to create model objects by writing simple classes. (These are also known as POCO classes, from "plain-old CLR objects.") You can then have the database created on the fly from your classes, which enables a very clean and rapid development workflow.

Adding Model Classes

In **Solution Explorer**, right click the *Models* folder, select **Add**, and then select **Class**.

Name the class "Movie".

Add the following five properties to the `Movie` class:

```
Public Class Movie
        Public Property ID() As Integer
        Public Property Title() As String
        Public Property ReleaseDate() As Date
        Public Property Genre() As String
        Public Property Price() As Decimal
End Class
```

We'll use the `Movie` class to represent movies in a database. Each instance of a `Movie` object will correspond to a row within a database table, and each property of the `Movie` class will map to a column in the table.

In the same file, add the following `MovieDBContext` class:

```
Public Class MovieDBContext
    Inherits DbContext
    Public Property Movies() As DbSet(Of Movie)
End Class
```

The `MovieDBContext` class represents the Entity Framework movie database context, which handles fetching, storing, and updating `Movie` class instances in a database. The `MovieDBContext` derives from the `DbContext` base class provided by the Entity Framework. For more information about `DbContext` and `DbSet`, see Productivity Improvements for the Entity Framework.

In order to be able to reference `DbContext` and `DbSet`, you need to add the following `imports` statement at the top of the file:

```
Imports System.Data.Entity
```

The complete *Movie.vb* file is shown below.

```
Imports System.Data.Entity

Public Class Movie
        Public Property ID() As Integer
        Public Property Title() As String
        Public Property ReleaseDate() As Date
        Public Property Genre() As String
        Public Property Price() As Decimal
End Class

Public Class MovieDBContext
    Inherits DbContext
    Public Property Movies() As DbSet(Of Movie)
End Class
```

Creating a Connection String and Working with SQL Server Compact

The `MovieDBContext` class you created handles the task of connecting to the database and mapping `Movie` objects to database records. One question you might ask, though, is how to specify which database it will connect to. You'll do that by adding connection information in the *Web.config* file of the application.

Open the application root *Web.config* file. (Not the *Web.config* file in the *Views* folder.) The image below show both *Web.config* files; open the *Web.config* file circled in red.

Add the following connection string to the `<connectionStrings>` element in the *Web.config* file.

```
<add name="MovieDBContext"
         connectionString="Data Source=|DataDirectory|Movies.sdf"
         providerName="System.Data.SqlServerCe.4.0"/>
```

The following example shows a portion of the *Web.config* file with the new connection string added:

```
<configuration>
  <connectionStrings>
    <add name="MovieDBContext"
         connectionString="Data Source=|DataDirectory|Movies.sdf"
         providerName="System.Data.SqlServerCe.4.0"/>
    <add name="ApplicationServices"
         connectionString="data source=.\SQLEXPRESS;Integrated
Security=SSPI;AttachDBFilename=|DataDirectory|aspnetdb.mdf;User Instance=true"
         providerName="System.Data.SqlClient" />
  </connectionStrings>
```

This small amount of code and XML is everything you need to write in order to represent and store the movie data in a database.

Next, you'll build a new `MoviesController` class that you can use to display the movie data and allow users to create new movie listings.

Accessing your Model's Data from a Controller (VB)

2/20/2020 • 6 minutes to read • Edit Online

by Rick Anderson

This tutorial will teach you the basics of building an ASP.NET MVC Web application using Microsoft Visual Web Developer 2010 Express Service Pack 1, which is a free version of Microsoft Visual Studio. Before you start, make sure you've installed the prerequisites listed below. You can install all of them by clicking the following link: Web Platform Installer. Alternatively, you can individually install the prerequisites using the following links:

- Visual Studio Web Developer Express SP1 prerequisites
- ASP.NET MVC 3 Tools Update
- SQL Server Compact 4.0(runtime + tools support)

If you're using Visual Studio 2010 instead of Visual Web Developer 2010, install the prerequisites by clicking the following link: Visual Studio 2010 prerequisites.

A Visual Web Developer project with VB.NET source code is available to accompany this topic. Download the VB.NET version. If you prefer C#, switch to the C# version of this tutorial.

In this section, you'll create a new `MoviesController` class and write code that retrieves the movie data and displays it in the browser using a view template. Be sure to build your application before proceeding.

Right-click the *Controllers* folder and create a new `MoviesController` controller. Select the following options:

- Controller name: **MoviesController**. (This is the default.)
- Template: **Controller with read/write actions and views, using Entity Framework**.
- Model class: **Movie (MvcMovie.Models)**.
- Data context class: **MovieDBContext (MvcMovie.Models)**.
- Views: **Razor (CSHTML)**. (The default.)

Click **Add**. Visual Web Developer creates the following files and folders:

- *A MoviesController.vb* file in the project's *Controllers* folder.
- A *Movies* folder in the project's *Views* folder.
- *Create.vbhtml, Delete.vbhtml, Details.vbhtml, Edit.vbhtml*, and *Index.vbhtml* in the new *Views\Movies* folder.

The ASP.NET MVC 3 scaffolding mechanism automatically created the CRUD (create, read, update, and delete) action methods and views for you. You now have a fully functional web application that lets you create, list, edit, and delete movie entries.

Run the application and browse to the `Movies` controller by appending */Movies* to the URL in the address bar of your browser. Because the application is relying on the default routing (defined in the *Global.asax* file), the browser request `http://localhost:xxxxx/Movies` is routed to the default `Index` action method of the `Movies` controller. In other words, the browser request `http://localhost:xxxxx/Movies` is effectively the same as the browser request `http://localhost:xxxxx/Movies/Index`. The result is an empty list of movies, because you haven't added any yet.

Creating a Movie

Select the **Create New** link. Enter some details about a movie and then click the **Create** button.

Clicking the **Create** button causes the form to be posted to the server, where the movie information is saved in the database. You're then redirected to the */Movies* URL, where you can see the newly created movie in the listing.

Create a couple more movie entries. Try the **Edit**, **Details**, and **Delete** links, which are all functional.

Examining the Generated Code

Open the *Controllers\MoviesController.vb* file and examine the generated `Index` method. A portion of the movie controller with the `Index` method is shown below.

```
Public Class MoviesController
        Inherits System.Web.Mvc.Controller

        Private db As MovieDBContext = New MovieDBContext

        '
        ' GET: /Movies/

        Function Index() As ViewResult
            Return View(db.Movies.ToList())
        End Function
```

The following line from the `MoviesController` class instantiates a movie database context, as described previously. You can use the movie database context to query, edit, and delete movies.

```
Private db As MovieDBContext = New MovieDBContex
```

A request to the `Movies` controller returns all the entries in the `Movies` table of the movie database and then passes the results to the `Index` view.

Strongly Typed Models and the @model Keyword

Earlier in this tutorial, you saw how a controller can pass data or objects to a view template using the `ViewBag` object. The `ViewBag` is a dynamic object that provides a convenient late-bound way to pass information to a view.

ASP.NET MVC also provides the ability to pass strongly typed data or objects to a view template. This strongly typed approach enables better compile-time checking of your code and richer IntelliSense in the Visual Web

Developer editor. We're using this approach with the `MoviesController` class and *Index.vbhtml* view template.

Notice how the code creates a `List` object when it calls the `View` helper method in the `Index` action method. The code then passes this `Movies` list from the controller to the view:

```
Function Index() As ViewResult
            Return View(db.Movies.ToList())
       End Function
```

By including a `@ModelType` statement at the top of the view template file, you can specify the type of object that the view expects. When you created the movie controller, Visual Web Developer automatically included the following `@model` statement at the top of the *Index.vbhtml* file:

```
@ModelType IEnumerable(Of MvcMovie.Movie)
```

This `@ModelType` directive allows you to access the list of movies that the controller passed to the view by using a `Model` object that's strongly typed. For example, in the *Index.vbhtml* template, the code loops through the movies by doing a `foreach` statement over the strongly typed `Model` object:

```
@For Each item In Model
    Dim currentItem = item
    @<tr>
        <td>
            @Html.DisplayFor(Function(modelItem) currentItem.Title)
        </td>
        <td>
            @Html.DisplayFor(Function(modelItem) currentItem.ReleaseDate)
        </td>
        <td>
            @Html.DisplayFor(Function(modelItem) currentItem.Genre)
        </td>
        <td>
            @Html.DisplayFor(Function(modelItem) currentItem.Price)
        </td>
        <td>
            @Html.ActionLink("Edit", "Edit", New With {.id = currentItem.ID}) |
            @Html.ActionLink("Details", "Details", New With {.id = currentItem.ID}) |
            @Html.ActionLink("Delete", "Delete", New With {.id = currentItem.ID})
        </td>
    </tr>
Next
```

Because the `Model` object is strongly typed (as an `IEnumerable<Movie>` object), each `item` object in the loop is typed as `Movie`. Among other benefits, this means that you get compile-time checking of the code and full IntelliSense support in the code editor:

Working with SQL Server Compact

Entity Framework Code First detected that the database connection string that was provided pointed to a `Movies` database that didn't exist yet, so Code First created the database automatically. You can verify that it's been created by looking in the *App_Data* folder. If you don't see the *Movies.sdf* file, click the **Show All Files** button in the **Solution Explorer** toolbar, click the **Refresh** button, and then expand the *App_Data* folder.

Double-click *Movies.sdf* to open **Server Explorer**. Then expand the **Tables** folder to see the tables that have been created in the database.

> **NOTE**
>
> If you get an error when you double-click *Movies.sdf*, make sure you've installed **Visual Studio 2010 SP1 Tools for SQL Server Compact 4.0**. (For links to the software, see the list of prerequisites in part 1 of this tutorial series.) If you install the release now, you'll have to close and re-open Visual Web Developer.

There are two tables, one for the `Movie` entity set and then the `EdmMetadata` table. The `EdmMetadata` table is used by the Entity Framework to determine when the model and the database are out of sync.

Right-click the `Movies` table and select **Show Table Data** to see the data you created.

Right-click the `Movies` table and select **Edit Table Schema**.

Notice how the schema of the `Movies` table maps to the `Movie` class you created earlier. Entity Framework Code First automatically created this schema for you based on your `Movie` class.

When you're finished, close the connection. (If you don't close the connection, you might get an error the next time you run the project).

You now have the database and a simple listing page to display content from it. In the next tutorial, we'll examine the rest of the scaffolded code and add a `SearchIndex` method and a `SearchIndex` view that lets you search for movies in this database.

Examining the Edit Methods and Edit View (VB)

9/16/2020 • 13 minutes to read • Edit Online

by Rick Anderson

This tutorial will teach you the basics of building an ASP.NET MVC Web application using Microsoft Visual Web Developer 2010 Express Service Pack 1, which is a free version of Microsoft Visual Studio. Before you start, make sure you've installed the prerequisites listed below. You can install all of them by clicking the following link: Web Platform Installer. Alternatively, you can individually install the prerequisites using the following links:

- Visual Studio Web Developer Express SP1 prerequisites
- ASP.NET MVC 3 Tools Update
- SQL Server Compact 4.0(runtime + tools support)

If you're using Visual Studio 2010 instead of Visual Web Developer 2010, install the prerequisites by clicking the following link: Visual Studio 2010 prerequisites.

A Visual Web Developer project with VB.NET source code is available to accompany this topic. Download the VB.NET version. If you prefer C#, switch to the C# version of this tutorial.

In this section, you'll examine the generated action methods and views for the movie controller. Then you'll add a custom search page.

Run the application and browse to the `Movies` controller by appending */Movies* to the URL in the address bar of your browser. Hold the mouse pointer over an **Edit** link to see the URL that it links to.

The **Edit** link was generated by the `Html.ActionLink` method in the *Views\Movies\Index.vbhtml* view:

```
@Html.ActionLink("Edit", "Edit", New With {.id = currentItem.ID}) |
```

```
<td>
    @Html.ActionLink("Edit", "Edit", New With {.id = currentItem.ID}) |
    @ <Extension> Public Function ActionLink(linkText As String, actionName As String, routeValues As Object)
    @ Returns an anchor element (a element) that contains the virtual path of the specified action.
</td>
```

The `Html` object is a helper that's exposed using a property on the `WebViewPage` base class. The `ActionLink` method of the helper makes it easy to dynamically generate HTML hyperlinks that link to action methods on controllers. The first argument to the `ActionLink` method is the link text to render (for example, `<a>Edit Me</a>`). The second argument is the name of the action method to invoke. The final argument is an anonymous object that generates the route data (in this case, the ID of 4).

The generated link shown in the previous image is `http://localhost:xxxxx/Movies/Edit/4`. The default route takes the URL pattern `{controller}/{action}/{id}`. Therefore, ASP.NET translates `http://localhost:xxxxx/Movies/Edit/4` into a request to the `Edit` action method of the `Movies` controller with the parameter `ID` equal to 4.

You can also pass action method parameters using a query string. For example, the URL `http://localhost:xxxxx/Movies/Edit?ID=4` also passes the parameter `ID` of 4 to the `Edit` action method of the `Movies` controller.

Open the `Movies` controller. The two `Edit` action methods are shown below.

```
'
' GET: /Movies/Edit/5

Function Edit(id As Integer) As ViewResult
    Dim movie As Movie = db.Movies.Find(id)
    Return View(movie)
End Function

'
' POST: /Movies/Edit/5

<HttpPost()>
Function Edit(movie As Movie) As ActionResult
    If ModelState.IsValid Then
        db.Entry(movie).State = EntityState.Modified
        db.SaveChanges()
        Return RedirectToAction("Index")
    End If

    Return View(movie)
End Function
```

Notice the second `Edit` action method is preceded by the `HttpPost` attribute. This attribute specifies that overload of the `Edit` method can be invoked only for POST requests. You could apply the `HttpGet` attribute to the first edit method, but that's not necessary because it's the default. (We'll refer to action methods that are implicitly assigned the `HttpGet` attribute as `HttpGet` methods.)

The `HttpGet` `Edit` method takes the movie ID parameter, looks up the movie using the Entity Framework `Find` method, and returns the selected movie to the Edit view. When the scaffolding system created the Edit view, it examined the `Movie` class and created code to render `<label>` and `<input>` elements for each property of the class. The following example shows the Edit view that was generated:

```
@ModelType MvcMovie.Movie

@Code
    ViewData("Title") = "Edit"
End Code

<h2>Edit</h2>

<script src="@Url.Content("~/Scripts/jquery.validate.min.js")" type="text/javascript"></script>
<script src="@Url.Content("~/Scripts/jquery.validate.unobtrusive.min.js")" type="text/javascript"></script>

@Using Html.BeginForm()
    @Html.ValidationSummary(True)
    @<fieldset>
        <legend>Movie</legend>

        @Html.HiddenFor(Function(model) model.ID)

        <div class="editor-label">
            @Html.LabelFor(Function(model) model.Title)
        </div>
        <div class="editor-field">
            @Html.EditorFor(Function(model) model.Title)
            @Html.ValidationMessageFor(Function(model) model.Title)
        </div>

        <div class="editor-label">
            @Html.LabelFor(Function(model) model.ReleaseDate)
        </div>
        <div class="editor-field">
            @Html.EditorFor(Function(model) model.ReleaseDate)
            @Html.ValidationMessageFor(Function(model) model.ReleaseDate)
        </div>

        <div class="editor-label">
            @Html.LabelFor(Function(model) model.Genre)
        </div>
        <div class="editor-field">
            @Html.EditorFor(Function(model) model.Genre)
            @Html.ValidationMessageFor(Function(model) model.Genre)
        </div>

        <div class="editor-label">
            @Html.LabelFor(Function(model) model.Price)
        </div>
        <div class="editor-field">
            @Html.EditorFor(Function(model) model.Price)
            @Html.ValidationMessageFor(Function(model) model.Price)
        </div>

        <p>
            <input type="submit" value="Save" />
        </p>
    </fieldset>
End Using

<div>
    @Html.ActionLink("Back to List", "Index")
</div>
```

Notice how the view template has a `@ModelType MvcMovie.Models.Movie` statement at the top of the file — this specifies that the view expects the model for the view template to be of type `Movie`.

The scaffolded code uses several *helper methods* to streamline the HTML markup. The `Html.LabelFor` helper displays the name of the field ("Title", "ReleaseDate", "Genre", or "Price"). The `Html.EditorFor` helper displays an

HTML `<input>` element. The `Html.ValidationMessageFor` helper displays any validation messages associated with that property.

Run the application and navigate to the */Movies* URL. Click an **Edit** link. In the browser, view the source for the page. The HTML in the page looks like the following example. (The menu markup was excluded for clarity.)

```
<!DOCTYPE html>
<html>
<head>
    <meta charset="utf-8" />
    <title>Edit</title>
    <link href="/Content/Site.css" rel="stylesheet" type="text/css" />
    <script src="/Scripts/jquery-1.5.1.min.js" type="text/javascript"></script>
    <script src="/Scripts/modernizr-1.7.min.js" type="text/javascript"></script>
</head>
<body>
    <div class="page">
        <header>
            <div id="title">
                <h1>MVC Movie App</h1>
            </div>
           ...
        </header>
        <section id="main">

<h2>Edit</h2>

<script src="/Scripts/jquery.validate.min.js" type="text/javascript"></script>
<script src="/Scripts/jquery.validate.unobtrusive.min.js" type="text/javascript"></script>

<form action="/Movies/Edit/4" method="post">    <fieldset>
        <legend>Movie</legend>

        <input data-val="true" data-val-number="The field ID must be a number."
    data-val-required="The ID field is required." id="ID" name="ID" type="hidden" value="4" />

        <div class="editor-label">
            <label for="Title">Title</label>
        </div>
        <div class="editor-field">
            <input class="text-box single-line" id="Title" name="Title" type="text" value="Rio Bravo" />
            <span class="field-validation-valid" data-valmsg-for="Title" data-valmsg-replace="true"></span>
        </div>

        <div class="editor-label">
            <label for="ReleaseDate">ReleaseDate</label>
        </div>
        <div class="editor-field">
            <input class="text-box single-line" data-val="true" data-val-required="The ReleaseDate field is
required."
    id="ReleaseDate" name="ReleaseDate" type="text" value="4/15/1959 12:00:00 AM" />
            <span class="field-validation-valid" data-valmsg-for="ReleaseDate" data-valmsg-replace="true">
</span>
        </div>

        <div class="editor-label">
            <label for="Genre">Genre</label>
        </div>
        <div class="editor-field">
            <input class="text-box single-line" id="Genre" name="Genre" type="text" value="Western" />
            <span class="field-validation-valid" data-valmsg-for="Genre" data-valmsg-replace="true">></span>
        </div>

        <div class="editor-label">
            <label for="Price">Price</label>
        </div>
        <div class="editor-field">
```

```
            <input class="text-box single-line" data-val="true" data-val-number="The field Price must be a
number."
    data-val-required="The Price field is required." id="Price" name="Price" type="text" value="9.99" />
            <span class="field-validation-valid" data-valmsg-for="Price" data-valmsg-replace="true"></span>
        </div>

        <p>
            <input type="submit" value="Save" />
        </p>
    </fieldset>
</form>
<div>
    <a href="/Movies">Back to List</a>
</div>

        </section>
        <footer>
        </footer>
    </div>
</body>
</html>
```

The `<input>` elements are in an HTML `<form>` element whose `action` attribute is set to post to the */Movies/Edit* URL. The form data will be posted to the server when the **Edit** button is clicked.

Processing the POST Request

The following listing shows the `HttpPost` version of the `Edit` action method.

```
'
' POST: /Movies/Edit/5

<HttpPost()>
Function Edit(movie As Movie) As ActionResult
    If ModelState.IsValid Then
        db.Entry(movie).State = EntityState.Modified
        db.SaveChanges()
        Return RedirectToAction("Index")
    End If

    Return View(movie)
End Function
```

The ASP.NET framework model binder takes the posted form values and creates a `Movie` object that's passed as the `movie` parameter. The `ModelState.IsValid` check in the code verifies that the data submitted in the form can be used to modify a `Movie` object. If the data is valid, the code saves the movie data to the `Movies` collection of the `MovieDBContext` instance. The code then saves the new movie data to the database by calling the `SaveChanges` method of `MovieDBContext`, which persists changes to the database. After saving the data, the code redirects the user to the `Index` action method of the `MoviesController` class, which causes the updated movie to be displayed in the listing of movies.

If the posted values aren't valid, they are redisplayed in the form. The `Html.ValidationMessageFor` helpers in the *Edit.vbhtml* view template take care of displaying appropriate error messages.

Note about locales If you normally work with a locale other than English, see Supporting ASP.NET MVC 3 Validation with Non-English Locales.

Making the Edit Method More Robust

The `HttpGet` `Edit` method generated by the scaffolding system doesn't check that the ID that's passed to it is valid. If a user removes the ID segment from the URL (`http://localhost:xxxxx/Movies/Edit`), the following error is displayed:

A user could also pass an ID that doesn't exist in the database, such as `http://localhost:xxxxx/Movies/Edit/1234`. You can make two changes to the `HttpGet` `Edit` action method to address this limitation. First, change the `ID` parameter to have a default value of zero when an ID isn't explicitly passed. You can also check that the `Find`

method actually found a movie before returning the movie object to the view template. The updated `Edit` method is shown below.

```
Public Function Edit(Optional ByVal id As Integer = 0) As ActionResult
    Dim movie As Movie = db.Movies.Find(id)
    If movie Is Nothing Then
        Return HttpNotFound()
    End If
    Return View(movie)
End Function
```

If no movie is found, the `HttpNotFound` method is called.

All the `HttpGet` methods follow a similar pattern. They get a movie object (or list of objects, in the case of `Index`), and pass the model to the view. The `Create` method passes an empty movie object to the Create view. All the methods that create, edit, delete, or otherwise modify data do so in the `HttpPost` overload of the method. Modifying data in an HTTP GET method is a security risk, as described in the blog post entry ASP.NET MVC Tip #46 – Don't use Delete Links because they create Security Holes. Modifying data in a GET method also violates HTTP best practices and the architectural REST pattern, which specifies that GET requests should not change the state of your application. In other words, performing a GET operation should be a safe operation that has no side effects.

Adding a Search Method and Search View

In this section you'll add a `SearchIndex` action method that lets you search movies by genre or name. This will be available using the */Movies/SearchIndex* URL. The request will display an HTML form that contains input elements that a user can fill in in order to search for a movie. When a user submits the form, the action method will get the search values posted by the user and use the values to search the database.

Displaying the SearchIndex Form

Start by adding a `SearchIndex` action method to the existing `MoviesController` class. The method will return a view that contains an HTML form. Here's the code:

```
Public Function SearchIndex(ByVal searchString As String) As ActionResult
    Dim movies = From m In db.Movies
                 Select m

    If Not String.IsNullOrEmpty(searchString) Then
        movies = movies.Where(Function(s) s.Title.Contains(searchString))
    End If
    Return View(movies)
End Function
```

The first line of the `SearchIndex` method creates the following LINQ query to select the movies:

```
Dim movies = From m In db.Movies    Select m
```

The query is defined at this point, but hasn't yet been run against the data store.

If the `searchString` parameter contains a string, the movies query is modified to filter on the value of the search string, using the following code:

If Not String.IsNullOrEmpty(searchString) Then
movies = movies.Where(Function(s) s.Title.Contains(searchString))
End If

LINQ queries are not executed when they are defined or when they are modified by calling a method such as `Where` or `OrderBy`. Instead, query execution is deferred, which means that the evaluation of an expression is delayed until its realized value is actually iterated over or the `ToList` method is called. In the `SearchIndex` sample, the query is executed in the SearchIndex view. For more information about deferred query execution, see Query Execution.

Now you can implement the `SearchIndex` view that will display the form to the user. Right-click inside the `SearchIndex` method and then click **Add View**. In the **Add View** dialog box, specify that you're going to pass a `Movie` object to the view template as its model class. In the **Scaffold template** list, choose **List**, then click **Add**.

When you click the **Add** button, the *Views\Movies\SearchIndex.vbhtml* view template is created. Because you selected **List** in the **Scaffold template** list, Visual Web Developer automatically generated (scaffolded) some default content in the view. The scaffolding created an HTML form. It examined the `Movie` class and created code to render `<label>` elements for each property of the class. The listing below shows the Create view that was generated:

```
@ModelType IEnumerable(Of MvcMovie.Movie)

@Code
    ViewData("Title") = "SearchIndex"
End Code

<h2>SearchIndex</h2>

<p>
    @Html.ActionLink("Create New", "Create")
</p>
<table>
    <tr>
        <th>
            Title
        </th>
        <th>
            ReleaseDate
        </th>
        <th>
            Genre
        </th>
        <th>
            Price
        </th>
        <th></th>
    </tr>

@For Each item In Model
    Dim currentItem = item
    @<tr>
        <td>
            @Html.DisplayFor(Function(modelItem) currentItem.Title)
        </td>
        <td>
            @Html.DisplayFor(Function(modelItem) currentItem.ReleaseDate)
        </td>
        <td>
            @Html.DisplayFor(Function(modelItem) currentItem.Genre)
        </td>
        <td>
            @Html.DisplayFor(Function(modelItem) currentItem.Price)
        </td>
        <td>
            @Html.ActionLink("Edit", "Edit", New With {.id = currentItem.ID}) |
            @Html.ActionLink("Details", "Details", New With {.id = currentItem.ID}) |
            @Html.ActionLink("Delete", "Delete", New With {.id = currentItem.ID})
        </td>
    </tr>
Next

</table>
```

Run the application and navigate to */Movies/SearchIndex*. Append a query string such as `?searchString=ghost` to the URL. The filtered movies are displayed.

If you change the signature of the `SearchIndex` method to have a parameter named `id`, the `id` parameter will match the `{id}` placeholder for the default routes set in the *Global.asax* file.

```
{controller}/{action}/{id}
```

The modified `SearchIndex` method would look as follows:

```
Public Function SearchIndex(ByVal id As String) As ActionResult
Dim searchString As String = id
Dim movies = From m In db.Movies
             Select m

If Not String.IsNullOrEmpty(searchString) Then
    movies = movies.Where(Function(s) s.Title.Contains(searchString))
End If

Return View(movies)
End Function
```

You can now pass the search title as route data (a URL segment) instead of as a query string value.

However, you can't expect users to modify the URL every time they want to search for a movie. So now you you'll add UI to help them filter movies. If you changed the signature of the `SearchIndex` method to test how to pass the route-bound ID parameter, change it back so that your `SearchIndex` method takes a string parameter named `searchString`:

Open the *Views\Movies\SearchIndex.vbhtml* file, and just after `@Html.ActionLink("Create New", "Create")`, add the following:

```
@Code
    ViewData("Title") = "SearchIndex"
    Using (Html.BeginForm())
         @<p> Title: @Html.TextBox("SearchString")
         <input type="submit" value="Filter" /></p>
        End Using
End Code
```

The `Html.BeginForm` helper creates an opening `<form>` tag. The `Html.BeginForm` helper causes the form to post to itself when the user submits the form by clicking the **Filter** button.

Run the application and try searching for a movie.

There's no `HttpPost` overload of the `SearchIndex` method. You don't need it, because the method isn't changing the state of the application, just filtering data. If you added the following `HttpPost` `SearchIndex` method, the action invoker would match the `HttpPost` `SearchIndex` method, and the `HttpPost` `SearchIndex` method would run as shown in the image below.

```
<HttpPost()>
 Public Function SearchIndex(ByVal fc As FormCollection, ByVal searchString As String) As String
     Return "<h3> From [HttpPost]SearchIndex: " & searchString & "</h3>"
 End Function
```

Adding Search by Genre

If you added the `HttpPost` version of the `SearchIndex` method, delete it now.

Next, you'll add a feature to let users search for movies by genre. Replace the `SearchIndex` method with the following code:

```
Public Function SearchIndex(ByVal movieGenre As String, ByVal searchString As String) As ActionResult
    Dim GenreLst = New List(Of String)()

    Dim GenreQry = From d In db.Movies
                   Order By d.Genre
                   Select d.Genre
    GenreLst.AddRange(GenreQry.Distinct())
    ViewBag.movieGenre = New SelectList(GenreLst)

    Dim movies = From m In db.Movies
                 Select m

    If Not String.IsNullOrEmpty(searchString) Then
        movies = movies.Where(Function(s) s.Title.Contains(searchString))
    End If

    If String.IsNullOrEmpty(movieGenre) Then
        Return View(movies)
    Else
        Return View(movies.Where(Function(x) x.Genre = movieGenre))
    End If

End Function
```

This version of the `SearchIndex` method takes an additional parameter, namely `movieGenre`. The first few lines of code create a `List` object to hold movie genres from the database.

The following code is a LINQ query that retrieves all the genres from the database.

```
Dim GenreQry = From d In db.Movies
                   Order By d.Genre
                   Select d.Genre
```

The code uses the `AddRange` method of the generic `List` collection to add all the distinct genres to the list. (Without the `Distinct` modifier, duplicate genres would be added — for example, comedy would be added twice in our sample). The code then stores the list of genres in the `ViewBag` object.

The following code shows how to check the `movieGenre` parameter. If it's not empty the code further constrains the movies query to limit the selected movies to the specified genre.

```
If String.IsNullOrEmpty(movieGenre) Then
        Return View(movies)
    Else
        Return View(movies.Where(Function(x) x.Genre = movieGenre))
    End If
```

Adding Markup to the SearchIndex View to Support Search by Genre

Add an `Html.DropDownList` helper to the *Views\Movies\SearchIndex.vbhtml* file, just before the `TextBox` helper. The completed markup is shown below:

```
<p>
    @Html.ActionLink("Create New", "Create")
    @Code
    ViewData("Title") = "SearchIndex"
    Using (Html.BeginForm())
         @<p> Genre: @Html.DropDownList("movieGenre", "All")
         Title: @Html.TextBox("SearchString")
         <input type="submit" value="Filter" /></p>
        End Using
End Code
</p>
```

Run the application and browse to */Movies/SearchIndex*. Try a search by genre, by movie name, and by both criteria.

In this section you examined the CRUD action methods and views generated by the framework. You created a search action method and view that let users search by movie title and genre. In the next section, you'll look at how to add a property to the `Movie` model and how to add an initializer that will automatically create a test database.

Adding a New Field to the Movie Model and Database Table (VB)

2/20/2020 • 6 minutes to read • Edit Online

by Rick Anderson

> This tutorial will teach you the basics of building an ASP.NET MVC Web application using Microsoft Visual Web Developer 2010 Express Service Pack 1, which is a free version of Microsoft Visual Studio. Before you start, make sure you've installed the prerequisites listed below. You can install all of them by clicking the following link: Web Platform Installer. Alternatively, you can individually install the prerequisites using the following links:
>
> - Visual Studio Web Developer Express SP1 prerequisites
> - ASP.NET MVC 3 Tools Update
> - SQL Server Compact 4.0(runtime + tools support)
>
> If you're using Visual Studio 2010 instead of Visual Web Developer 2010, install the prerequisites by clicking the following link: Visual Studio 2010 prerequisites.
>
> A Visual Web Developer project with VB.NET source code is available to accompany this topic. Download the VB.NET version. If you prefer C#, switch to the C# version of this tutorial.

In this section you'll make some changes to the model classes and learn how you can update the database schema to match the model changes.

Adding a Rating Property to the Movie Model

Start by adding a new `Rating` property to the existing `Movie` class. Open the *Movie.cs* file and add the `Rating` property like this one:

```
Public Property Rating() As String
```

The complete `Movie` class now looks like the following code:

```
Public Class Movie
    Public Property ID() As Integer
    Public Property Title() As String
    Public Property ReleaseDate() As Date
    Public Property Genre() As String
    Public Property Price() As Decimal
    Public Property Rating() As String
End Class
```

Recompile the application using the **Debug** >**Build Movie** menu command.

Now that you've updated the `Model` class, you also need to update the *\Views\Movies\Index.vbhtml* and *\Views\Movies\Create.vbhtml* view templates in order to support the new `Rating` property.

Open the *\Views\Movies\Index.vbhtml* file and add a `<th>Rating</th>` column heading just after the **Price** column. Then add a `<td>` column near the end of the template to render the `@item.Rating` value. Below is what the

updated *Index.vbhtml* view template looks like:

```
<table>
    <tr>
        <th>            Title        </th>
        <th>            ReleaseDate        </th>
        <th>            Genre        </th>
        <th>            Price        </th>
        <th>Rating</th>
        <th></th>
    </tr>

@For Each item In Model
    Dim currentItem = item
    @<tr>
        <td>
            @Html.DisplayFor(Function(modelItem) currentItem.Title)
        </td>
        <td>
            @Html.DisplayFor(Function(modelItem) currentItem.ReleaseDate)
        </td>
        <td>
            @Html.DisplayFor(Function(modelItem) currentItem.Genre)
        </td>
        <td>
            @Html.DisplayFor(Function(modelItem) currentItem.Price)
        </td>
         <td>
            @Html.DisplayFor(Function(modelItem) currentItem.Rating)
        </td>
        <td>
            @Html.ActionLink("Edit", "Edit", New With {.id = currentItem.ID}) |
            @Html.ActionLink("Details", "Details", New With {.id = currentItem.ID}) |
            @Html.ActionLink("Delete", "Delete", New With {.id = currentItem.ID})
        </td>
    </tr>
Next

</table>
```

Next, open the *\Views\Movies\Create.vbhtml* file and add the following markup near the end of the form. This renders a text box so that you can specify a rating when a new movie is created.

```
<div class="editor-label">
     @Html.LabelFor(Function(model) model.Rating)
 </div>
 <div class="editor-field">
     @Html.EditorFor(Function(model) model.Rating)
     @Html.ValidationMessageFor(Function(model) model.Rating)
 </div>
```

Managing Model and Database Schema Differences

You've now updated the application code to support the new `Rating` property.

Now run the application and navigate to the */Movies* URL. When you do this, though, you'll see the following error:

You're seeing this error because the updated `Movie` model class in the application is now different than the schema of the `Movie` table of the existing database. (There's no `Rating` column in the database table.)

By default, when you use Entity Framework Code First to automatically create a database, as you did earlier in this tutorial, Code First adds a table to the database to help track whether the schema of the database is in sync with the model classes it was generated from. If they aren't in sync, the Entity Framework throws an error. This makes it easier to track down issues at development time that you might otherwise only find (by obscure errors) at run time. The sync-checking feature is what causes the error message to be displayed that you just saw.

There are two approaches to resolving the error:

1. Have the Entity Framework automatically drop and re-create the database based on the new model class schema. This approach is very convenient when doing active development on a test database, because it allows you to quickly evolve the model and database schema together. The downside, though, is that you lose existing data in the database — so you *don't* want to use this approach on a production database!
2. Explicitly modify the schema of the existing database so that it matches the model classes. The advantage of this approach is that you keep your data. You can make this change either manually or by creating a database change script.

For this tutorial, we'll use the first approach — you'll have the Entity Framework Code First automatically re-create the database anytime the model changes.

Automatically Re-Creating the Database on Model Changes

Let's update the application so that Code First automatically drops and re-creates the database anytime you change the model for the application.

> **NOTE**
>
> **Warning** You should enable this approach of automatically dropping and re-creating the database only when you're using a development or test database, and *never* on a production database that contains real data. Using it on a production server can lead to data loss.

In **Solution Explorer**, right click the *Models* folder, select **Add**, and then select **Class**.

Name the class "MovieInitializer". Update the `MovieInitializer` class to contain the following code:

```
using System;
Imports System
Imports System.Collections.Generic
Imports System.Data.Entity

Namespace MvcMovie.Models
    Public Class MovieInitializer
        Inherits DropCreateDatabaseIfModelChanges(Of MovieDBContext)
        Protected Overrides Sub Seed(ByVal context As MovieDBContext)
            Dim movies = New List(Of Movie) From {
             New Movie With {.Title = "When Harry Met Sally", .ReleaseDate = Date.Parse("1989-1-11"), .Genre =
"Romantic Comedy", .Rating = "R", .Price = 7.99D},
             New Movie With {.Title = "Ghostbusters ", .ReleaseDate = Date.Parse("1984-3-13"), .Genre =
"Comedy", .Rating = "R", .Price = 8.99D},
             New Movie With {.Title = "Ghostbusters 2", .ReleaseDate = Date.Parse("1986-2-23"), .Genre =
"Comedy", .Rating = "R", .Price = 9.99D},
             New Movie With {.Title = "Rio Bravo", .ReleaseDate = Date.Parse("1959-4-15"), .Genre = "Western",
.Rating = "R", .Price = 3.99D}}

            movies.ForEach(Function(d) context.Movies.Add(d))
        End Sub
    End Class
End Namespace
```

The `MovieInitializer` class specifies that the database used by the model should be dropped and automatically re-created if the model classes ever change. The code includes a `Seed` method to specify some default data to automatically add to the database any time it's created (or re-created). This provides a useful way to populate the database with some sample data, without requiring you to manually populate it each time you make a model change.

Now that you've defined the `MovieInitializer` class, you'll want to wire it up so that each time the application runs, it checks whether the model classes are different from the schema in the database. If they are, you can run

the initializer to re-create the database to match the model and then populate the database with the sample data.

Open the *Global.asax* file that's at the root of the `MvcMovies` project:

The *Global.asax* file contains the class that defines the entire application for the project, and contains an `Application_Start` event handler that runs when the application first starts.

Find the `Application_Start` method and add a call to `Database.SetInitializer` at the beginning of the method, as shown below:

```
Sub Application_Start()
        System.Data.Entity.Database.SetInitializer(Of MovieDBContext)(New MvcMovie.Models.MovieInitializer())

        AreaRegistration.RegisterAllAreas()

        RegisterGlobalFilters(GlobalFilters.Filters)
        RegisterRoutes(RouteTable.Routes)
    End Sub
```

The `Database.SetInitializer` statement you just added indicates that the database used by the `MovieDBContext` instance should be automatically deleted and re-created if the schema and the database don't match. And as you saw, it will also populate the database with the sample data that's specified in the `MovieInitializer` class.

Close the *Global.asax* file.

Re-run the application and navigate to the */Movies* URL. When the application starts, it detects that the model structure no longer matches the database schema. It automatically re-creates the database to match the new model structure and populates the database with the sample movies:

Click the **Create New** link to add a new movie. Note that you can add a rating.

Click **Create**. The new movie, including the rating, now shows up in the movies listing:

In this section you saw how you can modify model objects and keep the database in sync with the changes. You also learned a way to populate a newly created database with sample data so you can try out scenarios. Next, let's look at how you can add richer validation logic to the model classes and enable some business rules to be enforced.

Adding Validation to the Model (VB)

2/20/2020 • 8 minutes to read • Edit Online

by Rick Anderson

> This tutorial will teach you the basics of building an ASP.NET MVC Web application using Microsoft Visual Web Developer 2010 Express Service Pack 1, which is a free version of Microsoft Visual Studio. Before you start, make sure you've installed the prerequisites listed below. You can install all of them by clicking the following link: Web Platform Installer. Alternatively, you can individually install the prerequisites using the following links:
>
> - Visual Studio Web Developer Express SP1 prerequisites
> - ASP.NET MVC 3 Tools Update
> - SQL Server Compact 4.0(runtime + tools support)
>
> If you're using Visual Studio 2010 instead of Visual Web Developer 2010, install the prerequisites by clicking the following link: Visual Studio 2010 prerequisites.
>
> A Visual Web Developer project with VB.NET source code is available to accompany this topic. Download the VB.NET version. If you prefer C#, switch to the C# version of this tutorial.

In this section you'll add validation logic to the `Movie` model, and you'll ensure that the validation rules are enforced any time a user attempts to create or edit a movie using the application.

Keeping Things DRY

One of the core design tenets of ASP.NET MVC is DRY ("Don't Repeat Yourself"). ASP.NET MVC encourages you to specify functionality or behavior only once, and then have it be reflected everywhere in an application. This reduces the amount of code you need to write and makes the code you do write much easier to maintain.

The validation support provided by ASP.NET MVC and Entity Framework Code First is a great example of the DRY principle in action. You can declaratively specify validation rules in one place (in the model class) and then those rules are enforced everywhere in the application.

Let's look at how you can take advantage of this validation support in the movie application.

Adding Validation Rules to the Movie Model

You'll begin by adding some validation logic to the `Movie` class.

Open the *Movie.vb* file. Add a `Imports` statement at the top of the file that references the `System.ComponentModel.DataAnnotations` namespace:

```
Imports System.ComponentModel.DataAnnotations
```

The namespace is part of the .NET Framework. It provides a built-in set of validation attributes that you can apply declaratively to any class or property.

Now update the `Movie` class to take advantage of the built-in `Required`, `StringLength`, and `Range` validation attributes. Use the following code as an example of where to apply the attributes.

```
Public Class Movie
    Public Property ID() As Integer

    <Required(ErrorMessage:="Title is required")>
    Public Property Title() As String

    <Required(ErrorMessage:="Date is required")>
    Public Property ReleaseDate() As Date

    <Required(ErrorMessage:="Genre must be specified")>
    Public Property Genre() As String

    <Required(ErrorMessage:="Price Required"), Range(1, 100, ErrorMessage:="Price must be between $1 and
$100")>
    Public Property Price() As Decimal

    <StringLength(5)>
    Public Property Rating() As String
End Class
```

The validation attributes specify behavior that you want to enforce on the model properties they are applied to. The `Required` attribute indicates that a property must have a value; in this sample, a movie has to have values for the `Title`, `ReleaseDate`, `Genre`, and `Price` properties in order to be valid. The `Range` attribute constrains a value to within a specified range. The `StringLength` attribute lets you set the maximum length of a string property, and optionally its minimum length.

Code First ensures that the validation rules you specify on a model class are enforced before the application saves changes in the database. For example, the code below will throw an exception when the `SaveChanges` method is called, because several required `Movie` property values are missing and the price is zero (which is out of the valid range).

```
Dim db As New MovieDBContext()

Dim movie As New Movie()
movie.Title = "Gone with the Wind"
movie.Price = 0.0D

db.Movies.Add(movie)
db.SaveChanges() ' <= Will throw validation exception
```

Having validation rules automatically enforced by the .NET Framework helps make your application more robust. It also ensures that you can't forget to validate something and inadvertently let bad data into the database.

Here's a complete code listing for the updated *Movie.vb* file:

```
Imports System.Data.Entity
Imports System.ComponentModel.DataAnnotations

Public Class Movie
    Public Property ID() As Integer

    <Required(ErrorMessage:="Title is required")>
    Public Property Title() As String

    <Required(ErrorMessage:="Date is required")>
    Public Property ReleaseDate() As Date

    <Required(ErrorMessage:="Genre must be specified")>
    Public Property Genre() As String

    <Required(ErrorMessage:="Price Required"), Range(1, 100, ErrorMessage:="Price must be between $1 and
$100")>
    Public Property Price() As Decimal

    <StringLength(5)>
    Public Property Rating() As String
End Class

Public Class MovieDBContext
    Inherits DbContext
    Public Property Movies() As DbSet(Of Movie)
End Class
```

Validation Error UI in ASP.NET MVC

Re-run the application and navigate to the */Movies* URL.

Click the **Create Movie** link to add a new movie. Fill out the form with some invalid values and then click the **Create** button.

Notice how the form has automatically used a background color to highlight the text boxes that contain invalid data and has emitted an appropriate validation error message next to each one. The error messages match the error strings you specified when you annotated the `Movie` class. The errors are enforced both client-side (using JavaScript) and server-side (in case a user has JavaScript disabled).

A real benefit is that you didn't need to change a single line of code in the `MoviesController` class or in the *Create.vbhtml* view in order to enable this validation UI. The controller and views you created earlier in this tutorial automatically picked up the validation rules that you specified using attributes on the `Movie` model class.

How Validation Occurs in the Create View and Create Action Method

You might wonder how the validation UI was generated without any updates to the code in the controller or views. The next listing shows what the `Create` methods in the `MovieController` class look like. They're unchanged from how you created them earlier in this tutorial.

```
'
' GET: /Movies/Create

Function Create() As ViewResult
    Return View()
End Function

'
' POST: /Movies/Create

<HttpPost()>
Function Create(movie As Movie) As ActionResult
    If ModelState.IsValid Then
        db.Movies.Add(movie)
        db.SaveChanges()
        Return RedirectToAction("Index")
    End If

    Return View(movie)
End Function
```

The first action method displays the initial Create form. The second handles the form post. The second `Create` method calls `ModelState.IsValid` to check whether the movie has any validation errors. Calling this method evaluates any validation attributes that have been applied to the object. If the object has validation errors, the `Create` method redisplays the form. If there are no errors, the method saves the new movie in the database.

Below is the *Create.vbhtml* view template that you scaffolded earlier in the tutorial. It's used by the action methods shown above both to display the initial form and to redisplay it in the event of an error.

```
@ModelType MvcMovie.Movie

@Code
    ViewData("Title") = "Create"
End Code

<h2>Create</h2>

<script src="@Url.Content("~/Scripts/jquery.validate.min.js")" type="text/javascript"></script>
<script src="@Url.Content("~/Scripts/jquery.validate.unobtrusive.min.js")" type="text/javascript"></script>

@Using Html.BeginForm()
    @Html.ValidationSummary(True)
    @<fieldset>
        <legend>Movie</legend>

        <div class="editor-label">
            @Html.LabelFor(Function(model) model.Title)
        </div>
        <div class="editor-field">
            @Html.EditorFor(Function(model) model.Title)
            @Html.ValidationMessageFor(Function(model) model.Title)
        </div>

        <div class="editor-label">
            @Html.LabelFor(Function(model) model.ReleaseDate)
        </div>
        <div class="editor-field">
            @Html.EditorFor(Function(model) model.ReleaseDate)
            @Html.ValidationMessageFor(Function(model) model.ReleaseDate)
        </div>

        <div class="editor-label">
            @Html.LabelFor(Function(model) model.Genre)
        </div>
        <div class="editor-field">
            @Html.EditorFor(Function(model) model.Genre)
            @Html.ValidationMessageFor(Function(model) model.Genre)
        </div>

        <div class="editor-label">
            @Html.LabelFor(Function(model) model.Price)
        </div>
        <div class="editor-field">
            @Html.EditorFor(Function(model) model.Price)
            @Html.ValidationMessageFor(Function(model) model.Price)
        </div>

 <div class="editor-label">
     @Html.LabelFor(Function(model) model.Rating)
 </div>
 <div class="editor-field">
     @Html.EditorFor(Function(model) model.Rating)
     @Html.ValidationMessageFor(Function(model) model.Rating)
 </div>

        <p>
            <input type="submit" value="Create" />
        </p>
    </fieldset>
End Using

<div>
    @Html.ActionLink("Back to List", "Index")
</div>
```

Notice how the code uses an `Html.EditorFor` helper to output the `<input>` element for each `Movie` property. Next to this helper is a call to the `Html.ValidationMessageFor` helper method. These two helper methods work with the model object that's passed by the controller to the view (in this case, a `Movie` object). They automatically look for validation attributes specified on the model and display error messages as appropriate.

What's really nice about this approach is that neither the controller nor the Create view template knows anything about the actual validation rules being enforced or about the specific error messages displayed. The validation rules and the error strings are specified only in the `Movie` class.

If you want to change the validation logic later, you can do so in exactly one place. You won't have to worry about different parts of the application being inconsistent with how the rules are enforced — all validation logic will be defined in one place and used everywhere. This keeps the code very clean, and makes it easy to maintain and evolve. And it means that you'll be fully honoring the DRY principle.

Adding Formatting to the Movie Model

Open the *Movie.vb* file. The `System.ComponentModel.DataAnnotations` namespace provides formatting attributes in addition to the built-in set of validation attributes. You'll apply the `DisplayFormat` attribute and a `DataType` enumeration value to the release date and to the price fields. The following code shows the `ReleaseDate` and `Price` properties with the appropriate `DisplayFormat` attribute.

```
<DataType(DataType.Date)>
    Public Property ReleaseDate() As Date

     <DataType(DataType.Currency)>
    Public Property Price() As Decimal
```

Alternatively, you could explicitly set a `DataFormatString` value. The following code shows the release date property with a date format string (namely, "d"). You'd use this to specify that you don't want to time as part of the release date.

```
<DisplayFormat(DataFormatString:="{0:d}")>
    Public Property ReleaseDate() As Date
```

The following code formats the `Price` property as currency.

```
<DisplayFormat(DataFormatString:="{0:c}")>
    Public Property Price() As Decimal
```

The complete `Movie` class is shown below.

```
Public Class Movie
    Public Property ID() As Integer

    <Required(ErrorMessage:="Title is required")>
    Public Property Title() As String

    <Required(ErrorMessage:="Date is required")>
    <DataType(DataType.Date)>
    Public Property ReleaseDate() As Date

    <Required(ErrorMessage:="Genre must be specified")>
    Public Property Genre() As String

    <Required(ErrorMessage:="Price Required"), Range(1, 100, ErrorMessage:="Price must be between $1 and
$100")>
    <DataType(DataType.Currency)>
    Public Property Price() As Decimal

    <StringLength(5)>
    Public Property Rating() As String
End Class
```

Run the application and browse to the `Movies` controller.

In the next part of the series, we'll review the application and make some improvements to the automatically generated `Details` and `Delete` methods..

Improving the Details and Delete Methods (VB)

2/20/2020 • 5 minutes to read • Edit Online

by Rick Anderson

This tutorial will teach you the basics of building an ASP.NET MVC Web application using Microsoft Visual Web Developer 2010 Express Service Pack 1, which is a free version of Microsoft Visual Studio. Before you start, make sure you've installed the prerequisites listed below. You can install all of them by clicking the following link: Web Platform Installer. Alternatively, you can individually install the prerequisites using the following links:

- Visual Studio Web Developer Express SP1 prerequisites
- ASP.NET MVC 3 Tools Update
- SQL Server Compact 4.0(runtime + tools support)

If you're using Visual Studio 2010 instead of Visual Web Developer 2010, install the prerequisites by clicking the following link: Visual Studio 2010 prerequisites.

A Visual Web Developer project with VB.NET source code is available to accompany this topic. Download the VB.NET version. If you prefer C#, switch to the C# version of this tutorial.

In this part of the tutorial, you'll make some improvements to the automatically generated `Details` and `Delete` methods. These changes aren't required, but with just a few small bits of code, you can easily enhance the application.

Improving the Details and Delete Methods

When you scaffolded the `Movie` controller, ASP.NET MVC generated code that worked great, but that can be made more robust with just a few small changes.

Open the `Movie` controller and modify the `Details` method by returning `HttpNotFound` when a movie isn't found. You should also modify the `Details` method to set a default value for the ID that's passed to it. (You made similar changes to the `Edit` method in part 6 of this tutorial.) However, you must change the return type of the `Details` method from `ViewResult` to `ActionResult`, because the `HttpNotFound` method doesn't return a `ViewResult` object. The following example shows the modified `Details` method.

```
Public Function Details(Optional ByVal id As Integer = 0) As ActionResult
    Dim movie As Movie = db.Movies.Find(id)
    If movie Is Nothing Then
        Return HttpNotFound()
    End If
    Return View(movie)
End Function
```

Code First makes it easy to search for data using the `Find` method. An important security feature that we built into the method is that the code verifies that the `Find` method has found a movie before the code tries to do anything with it. For example, a hacker could introduce errors into the site by changing the URL created by the links from `http://localhost:xxxx/Movies/Details/1` to something like `http://localhost:xxxx/Movies/Details/12345` (or some other value that doesn't represent an actual movie). If you don't the check for a null movie, this could result in a database error.

Similarly, change the `Delete` and `DeleteConfirmed` methods to specify a default value for the ID parameter and to return `HttpNotFound` when a movie isn't found. The updated `Delete` methods in the `Movie` controller are shown below.

```
' GET: /Movies/Delete/5

 Public Function Delete(Optional ByVal id As Integer = 0) As ActionResult
     Dim movie As Movie = db.Movies.Find(id)
     If movie Is Nothing Then
         Return HttpNotFound()
     End If
     Return View(movie)
 End Function

 '
 ' POST: /Movies/Delete/5

 <HttpPost(), ActionName("Delete")>
 Public Function DeleteConfirmed(Optional ByVal id As Integer = 0) As ActionResult
     Dim movie As Movie = db.Movies.Find(id)
     If movie Is Nothing Then
         Return HttpNotFound()
     End If
     db.Movies.Remove(movie)
     db.SaveChanges()
     Return RedirectToAction("Index")
 End Function
```

Note that the `Delete` method doesn't delete the data. Performing a delete operation in response to a GET request (or for that matter, performing an edit operation, create operation, or any other operation that changes data) opens up a security hole. For more information about this, see Stephen Walther's blog entry ASP.NET MVC Tip #46 — Don't use Delete Links because they create Security Holes.

The `HttpPost` method that deletes the data is named `DeleteConfirmed` to give the HTTP POST method a unique signature or name. The two method signatures are shown below:

```
Public Function Delete(Optional ByVal id As Integer = 0) As ActionResult

 <HttpPost(), ActionName("Delete")>
 Public Function DeleteConfirmed(Optional ByVal id As Integer = 0) As ActionResult
```

The common language runtime (CLR) requires overloaded methods to have a unique signature (same name, different list of parameters). However, here you need two Delete methods -- one for GET and one for POST -- that both require the same signature. (They both need to accept a single integer as a parameter.)

To sort this out, you can do a couple of things. One is to give the methods different names. That's what we did in he preceding example. However, this introduces a small problem: ASP.NET maps segments of a URL to action methods by name, and if you rename a method, routing normally wouldn't be able to find that method. The solution is what you see in the example, which is to add the `ActionName("Delete")` attribute to the `DeleteConfirmed` method. This effectively performs mapping for the routing system so that a URL that includes */Delete/*for a POST request will find the `DeleteConfirmed` method.

Another way to avoid a problem with methods that have identical names and signatures is to artificially change the signature of the POST method to include an unused parameter. For example, some developers add a parameter type `FormCollection` that is passed to the POST method, and then simply don't use the parameter:

```
Public Function Delete(ByVal fcNotUsed As FormCollection, Optional ByVal id As Integer = 0) As ActionResult
Dim movie As Movie = db.Movies.Find(id)
If movie Is Nothing Then
    Return HttpNotFound()
End If
db.Movies.Remove(movie)
db.SaveChanges()
Return RedirectToAction("Index")
End Function
```

Wrapping Up

You now have a complete ASP.NET MVC application that stores data in a SQL Server Compact database. You can create, read, update, delete, and search for movies.

This basic tutorial got you started making controllers, associating them with views, and passing around hard-coded data. Then you created and designed a data model. Entity Framework Code First created a database from the data model on the fly, and the ASP.NET MVC scaffolding system automatically generated the action methods and views for basic CRUD operations. You then added a search form that let users search the database. You changed the database to include a new column of data, and then updated two pages to create and display this new data. You added validation by marking the data model with attributes from the `DataAnnotations` namespace. The resulting validation runs on the client and on the server.

If you'd like to deploy your application, it's helpful to first test the application on your local IIS 7 server. You can use this Web Platform Installer link to enable IIS setting for ASP.NET applications. See the following deployment links:

- ASP.NET Deployment Content Map
- Enabling IIS 7.x
- Web Application Projects Deployment

I now encourage you to move on to our intermediate-level Creating an Entity Framework Data Model for an ASP.NET MVC Application and MVC Music Store tutorials, to explore the ASP.NET articles on MSDN, and to check out the many videos and resources at https://asp.net/mvc to learn even more about ASP.NET MVC! The ASP.NET MVC forums are a great place to ask questions.

Enjoy!

— Scott Hanselman (http://hanselman.com and @shanselman on Twitter) and Rick Anderson blogs.msdn.com/rickAndy

Creating a MVC 3 Application with Razor and Unobtrusive JavaScript

4/10/2020 • 10 minutes to read • Edit Online

by Microsoft

The User List sample web application demonstrates how simple it is to create ASP.NET MVC 3 applications using the Razor view engine. The sample application shows how to use the new Razor view engine with ASP.NET MVC version 3 and Visual Studio 2010 to create a fictional User List website that includes functionality such as creating, displaying, editing, and deleting users.

This tutorial describes the steps that were taken in order to build the User List sample ASP.NET MVC 3 application. A Visual Studio project with C# and VB source code is available to accompany this topic: Download. If you have questions about this tutorial, please post them to the MVC forum.

Overview

The application you'll be building is a simple user list website. Users can enter, view, and update user information.

You can download the VB and C# completed project here.

Creating the Web Application

To start the tutorial, open Visual Studio 2010 and create a new project using the *ASP.NET MVC 3 Web Application* template. Name the application "Mvc3Razor".

In the **New ASP.NET MVC 3 Project** dialog, select **Internet Application**, select the Razor view engine, and then click **OK**.

In this tutorial you will not be using the ASP.NET membership provider, so you can delete all the files associated with logon and membership. In **Solution Explorer**, remove the following files and directories:

- *Controllers\AccountController*
- *Models\AccountModels*
- *Views\Shared_LogOnPartial*
- *Views\Account* (and all the files in this directory)

Edit the *_Layout.cshtml* file and replace the markup inside the `<div>` element named `logindisplay` with the message "Login Disabled". The following example shows the new markup:

```
<div id="logindisplay">
  Login Disabled
</div>
```

Adding the Model

In **Solution Explorer**, right-click the *Models* folder, select **Add**, and then click **Class**.

Name the class `UserModel`. Replace the contents of the *UserModel* file with the following code:

```
using System.ComponentModel.DataAnnotations;
using System.Collections.Generic;

namespace Mvc3Razor.Models {
    public class UserModel {

        [Required]
        [StringLength(6, MinimumLength = 3)]
        [Display(Name = "User Name")]
        [RegularExpression(@"(\S)+", ErrorMessage = "White space is not allowed")]
        [ScaffoldColumn(false)]
        public string UserName { get; set; }

        [Required]
        [StringLength(8, MinimumLength = 3)]
        [Display(Name = "First Name")]
        public string FirstName { get; set; }
        [Required]
        [StringLength(9, MinimumLength = 2)]
        [Display(Name = "Last Name")]
        public string LastName { get; set; }
        [Required()]
        public string City { get; set; }

    }

    public class Users {

        public Users() {
            _usrList.Add(new UserModel
            {
                UserName = "BenM",
                FirstName = "Ben",
                LastName = "Miller",
                City = "Seattle"
            });
            _usrList.Add(new UserModel
```

```
            {
                UserName = "AnnB",
                FirstName = "Ann",
                LastName = "Beebe",
                City = "Boston"
            });
        }

        public List<UserModel> _usrList = new List<UserModel>();

        public void Update(UserModel umToUpdate) {

            foreach (UserModel um in _usrList) {
                if (um.UserName == umToUpdate.UserName) {
                    _usrList.Remove(um);
                    _usrList.Add(umToUpdate);
                    break;
                }
            }
        }

        public void Create(UserModel umToUpdate) {
            foreach (UserModel um in _usrList) {
                if (um.UserName == umToUpdate.UserName) {
                    throw new System.InvalidOperationException("Duplicat username: " + um.UserName);
                }
            }
            _usrList.Add(umToUpdate);
        }

        public void Remove(string usrName) {

            foreach (UserModel um in _usrList) {
                if (um.UserName == usrName) {
                    _usrList.Remove(um);
                    break;
                }
            }
        }

        public  UserModel GetUser(string uid) {
            UserModel usrMdl = null;

            foreach (UserModel um in _usrList)
                if (um.UserName == uid)
                    usrMdl = um;

            return usrMdl;
        }

    }
}
```

The `UserModel` class represents users. Each member of the class is annotated with the Required attribute from the DataAnnotations namespace. The attributes in the DataAnnotations namespace provide automatic client- and server-side validation for web applications.

Open the `HomeController` class and add a `using` directive so that you can access the `UserModel` and `Users` classes:

```
using Mvc3Razor.Models;
```

Just after the `HomeController` declaration, add the following comment and the reference to a `Users` class:

```
public class HomeController : Controller {

// The __usrs class is replacement for a real data access strategy.
private static Users _usrs = new Users();
```

The `Users` class is a simplified, in-memory data store that you'll use in this tutorial. In a real application you would use a database to store user information. The first few lines of the `HomeController` file are shown in the following example:

```
using System.Web.Mvc;
using Mvc3Razor.Models;

namespace Mvc3Razor.Controllers {

    public class HomeController : Controller {

        // The __usrs class is replacement for a real data access strategy.
        private static Users _usrs = new Users();
```

Build the application so that the user model will be available to the scaffolding wizard in the next step.

Creating the Default View

The next step is to add an action method and view to display the users.

Delete the existing *Views\Home\Index* file. You will create a new *Index* file to display the users.

In the `HomeController` class, replace the contents of the `Index` method with the following code:

```
return View(_usrs._usrList);
```

Right-click inside the `Index` method and then click **Add View**.

Select the **Create a strongly-typed view** option. For **View data class**, select **Mvc3Razor.Models.UserModel**. (If you don't see **Mvc3Razor.Models.UserModel** in the **View data class** box, you need to build the project.) Make sure that the view engine is set to **Razor**. Set **View content** to **List** and then click **Add**.

The new view automatically scaffolds the user data that's passed to the `Index` view. Examine the newly generated *Views\Home\Index* file. The **Create New**, **Edit**, **Details**, and **Delete** links don't work, but the rest of the page is functional. Run the page. You see a list of users.

User List

Create New

	User Name	First Name	Last Name	City
Edit | Details | Delete	BenM	Ben	Miller	Seattle
Edit | Details | Delete	AnnB	Ann	Beebe	Boston

Open the *Index.cshtml* file and replace the `ActionLink` markup for **Edit**, **Details**, and **Delete** with the following code:

```
@Html.ActionLink("Edit", "Edit", new {  id=item.UserName  }) |
@Html.ActionLink("Details", "Details", new {  id=item.UserName  }) |
@Html.ActionLink("Delete", "Delete", new {  id=item.UserName  })
```

The user name is used as the ID to find the selected record in the **Edit**, **Details**, and **Delete** links.

Creating the Details View

The next step is to add a `Details` action method and view in order to display user details.

Add the following `Details` method to the home controller:

```
public ViewResult Details(string id) {
    return View(_usrs.GetUser(id));
}
```

Right-click inside the `Details` method and then select **Add View**. Verify that the **View data class** box contains **Mvc3Razor.Models.UserModel**. Set **View content** to **Details** and then click **Add**.

Run the application and select a details link. The automatic scaffolding shows each property in the model.

Creating the Edit View

Add the following `Edit` method to the home controller.

```
public ViewResult Edit(string id) {
    return View(_usrs.GetUser(id));
}

[HttpPost]
public ViewResult Edit(UserModel um) {

    if (!TryUpdateModel(um)) {
        ViewBag.updateError = "Update Failure";
        return View(um);
    }

    // ToDo: add persistent to DB.
    _usrs.Update(um);
    return View("Details", um);
}
```

Add a view as in the previous steps, but set **View content** to **Edit**.

Run the application and edit the first and last name of one of the users. If you violate any `DataAnnotation`

constraints that have been applied to the `UserModel` class, when you submit the form, you will see validation errors that are produced by server code. For example, if you change the first name "Ann" to "A", when you submit the form, the following error is displayed on the form:

```
The field First Name must be a string with a minimum length of 3 and a maximum length of 8.
```

In this tutorial, you're treating the user name as the primary key. Therefore, the user name property cannot be changed. In the *Edit.cshtml* file, just after the `Html.BeginForm` statement, set the user name to be a hidden field. This causes the property to be passed in the model. The following code fragment shows the placement of the `Hidden` statement:

```
<h2>Edit</h2>
    @using (Html.BeginForm()) {
@Html.Hidden("UserName", Model.UserName)
```

Replace the `TextBoxFor` and `ValidationMessageFor` markup for the user name with a `DisplayFor` call. The `DisplayFor` method displays the property as a read-only element. The following example shows the completed markup. The original `TextBoxFor` and `ValidationMessageFor` calls are commented out with the Razor begin-comment and end-comment characters (`@* *@`)

```
<div class="editor-label">
  @Html.LabelFor(model => model.UserName)
</div>

<div class="editor-field">
@*
  @Html.TextBoxFor(model => model.UserName)
  @Html.ValidationMessageFor(model => model.UserName)
*@
@Html.DisplayFor(model => model.UserName)
</div>
```

Enabling Client-Side Validation

To enable client-side validation in ASP.NET MVC 3, you must set two flags and you must include three JavaScript files.

Open the application's *Web.config* file. Verify `that ClientValidationEnabled` and `UnobtrusiveJavaScriptEnabled` are set to true in the application settings. The following fragment from the root *Web.config* file shows the correct settings:

```
<appSettings>
  <add key="ClientValidationEnabled" value="true"/>
  <add key="UnobtrusiveJavaScriptEnabled" value="true"/>
 </appSettings>
```

Setting `UnobtrusiveJavaScriptEnabled` to true enables unobtrusive Ajax and unobtrusive client validation. When you use unobtrusive validation, the validation rules are turned into HTML5 attributes. HTML5 attribute names can consist of only lowercase letters, numbers, and dashes.

Setting `ClientValidationEnabled` to true enables client-side validation. By setting these keys in the application *Web.config* file, you enable client validation and unobtrusive JavaScript for the entire application. You can also enable or disable these settings in individual views or in controller methods using the following code:

```
HtmlHelper.ClientValidationEnabled = true;
HtmlHelper.UnobtrusiveJavaScriptEnabled = true;
```

You also need to include several JavaScript files in the rendered view. An easy way to include the JavaScript in all views is to add them to the *Views\Shared_Layout.cshtml* file. Replace the `<head>` element of the *_Layout.cshtml* file with the following code:

```
<head>
  <title>@View.Title</title>
  <link href="@Url.Content("~/Content/Site.css")" rel="stylesheet" type="text/css" />
  <script src="https://ajax.aspnetcdn.com/ajax/jQuery/jquery-1.4.2.min.js"></script>
  <script src="https://ajax.aspnetcdn.com/ajax/jquery.validate/1.7/jquery.validate.min.js"></script>
  <script src="@Url.Content("~/Scripts/jquery.validate.unobtrusive.min.js")" type="text/javascript"></script>
</head>
```

The first two jQuery scripts are hosted by the Microsoft Ajax Content Delivery Network (CDN). By taking advantage of the Microsoft Ajax CDN, you can significantly improve the first-hit performance of your applications.

Run the application and click an edit link. View the page's source in the browser. The browser source shows many attributes of the form `data-val` (for data validation). When client validation and unobtrusive JavaScript is enabled, input fields with a client-validation rule contain the `data-val="true"` attribute to trigger unobtrusive client validation. For example, the `City` field in the model was decorated with the Required attribute, which results in the HTML shown in the following example:

```
<div class="editor-field">
  <input data-val="true" data-val-required="The City field is required." id="City" name="City" type="text"
value="Seattle" />
  <span class="field-validation-valid" data-valmsg-for="City" data-valmsg-replace="true"></span>
</div>
```

For each client-validation rule, an attribute is added that has the form `data-val-rulename="message"`. Using the `City` field example shown earlier, the required client-validation rule generates the `data-val-required` attribute and the message "The City field is required". Run the application, edit one of the users, and clear the `City` field. When you tab out of the field, you see a client-side validation error message.

Similarly, for each parameter in the client-validation rule, an attribute is added that has the form `data-val-rulename-paramname=paramvalue`. For example, the `FirstName` property is annotated with the StringLength attribute and specifies a minimum length of 3 and a maximum length of 8. The data validation rule named `length` has the parameter name `max` and the parameter value 8. The following shows the HTML that is generated for the `FirstName` field when you edit one of the users:

```
<input data-val="true"
       data-val-length="The field First Name must be a string with a minimum length of 3 and a maximum length
of 8."
       data-val-length-max="8"
       data-val-length-min="3"
       data-val-required="The First Name field is required."
       id="FirstName"
       name="FirstName"
       type="text"
       value="Ben" />
```

For more information about unobtrusive client validation, see the entry Unobtrusive Client Validation in ASP.NET MVC 3 in Brad Wilson's blog.

> **NOTE**
> In ASP.NET MVC 3 Beta, you sometimes need to submit the form in order to start client-side validation. This might be changed for the final release.

Creating the Create View

The next step is to add a `Create` action method and view in order to enable the user to create a new user. Add the following `Create` method to the home controller:

```
public ViewResult Create() {
    return View(new UserModel());
}

[HttpPost]
public ViewResult Create(UserModel um) {

    if (!TryUpdateModel(um)) {
        ViewBag.updateError = "Create Failure";
        return View(um);
    }

    // ToDo: add persistent to DB.
    _usrs.Create(um);
    return View("Details", um);
}
```

Add a view as in the previous steps, but set **View content** to **Create**.

Run the application, select the **Create** link, and add a new user. The `Create` method automatically takes advantage of client-side and server-side validation. Try to enter a user name that contains white space, such as "Ben X". When you tab out of the user name field, a client-side validation error (`White space is not allowed`) is displayed.

Add the Delete method

To complete the tutorial, add the following `Delete` method to the home controller:

```
public ViewResult Delete(string id) {
    return View(_usrs.GetUser(id));
}

[HttpPost]
public RedirectToRouteResult Delete(string id, FormCollection collection) {
    _usrs.Remove(id);
    return RedirectToAction("Index");
}
```

Add a `Delete` view as in the previous steps, setting **View content** to **Delete**.

You now have a simple but fully functional ASP.NET MVC 3 application with validation.

ASP.NET MVC 3 Music Store

2/20/2020 • 2 minutes to read • Edit Online

How to create the MVC Music Store application, a sample application that sells music albums online, and that implements site administration, user sign-in, and shopping cart functionality.

> The MVC Music Store is a tutorial application that introduces and explains step-by-step how to use ASP.NET MVC and Visual Studio for web development.
>
> The MVC Music Store is a lightweight sample store implementation which sells music albums online, and implements basic site administration, user sign-in, and shopping cart functionality.
>
> This tutorial series details all of the steps taken to build the ASP.NET MVC Music Store sample application. Part 1 covers Overview and File->New Project.

Overview

The MVC Music Store is a tutorial application that introduces and explains step-by-step how to use ASP.NET MVC and Visual Web Developer for web development. We'll be starting slowly, so beginner level web development experience is okay.

The application we'll be building is a simple music store. There are three main parts to the application: shopping, checkout, and administration.

Visitors can browse Albums by Genre:

They can view a single album and add it to their cart:

They can review their cart, removing any items they no longer want:

Proceeding to Checkout will prompt them to login or register for a user account.

After creating an account, they can complete the order by filling out shipping and payment information. To keep things simple, we're running an amazing promotion: everything's free if they enter promotion code "FREE"!

After ordering, they see a simple confirmation screen:

In addition to customer-facing pages, we'll also build an administrator section that shows a list of albums from which Administrators can Create, Edit, and Delete albums:

1. File -> New Project

Installing the software

This tutorial will begin by creating a new ASP.NET MVC 3 project using the free Visual Web Developer 2010 Express (which is free), and then we'll incrementally add features to create a complete functioning application. Along the way, we'll cover database access, form posting scenarios, data validation, using master pages for consistent page layout, using AJAX for page updates and validation, user login, and more.

You can follow along step by step, or you can download the completed application from MVC-Music-Store.

You can use either Visual Studio 2010 SP1 or Visual Web Developer 2010 Express SP1 (a free version of Visual Studio 2010) to build the application. We'll be using the SQL Server Compact (also free) to host the database. Before you start, make sure you've installed the prerequisites listed below.

- [Visual Studio Web Developer Express SP1 prerequisites]
- [ASP.NET MVC 3 Tools Update]
- [SQL Server Compact 4.0] - including both runtime and tools support

Creating a new ASP.NET MVC 3 project

We'll start by selecting "New Project" from the File menu in Visual Web Developer. This brings up the New Project dialog.

We'll select the Visual C# -> Web Templates group on the left, then choose the "ASP.NET MVC 3 Web Application" template in the center column. Name your project MvcMusicStore and press the OK button.

This will display a secondary dialog which allows us to make some MVC specific settings for our project. Select the following:

Project Template - select Empty

View Engine - select Razor

Use HTML5 semantic markup - checked

Verify that your settings are as shown below, then press the OK button.

This will create our project. Let's take a look at the folders that have been added to our application in the Solution Explorer on the right side.

The Empty MVC 3 template isn't completely empty – it adds a basic folder structure:

ASP.NET MVC makes use of some basic naming conventions for folder names:

FOLDER	PURPOSE
/Controllers	Controllers respond to input from the browser, decide what to do with it, and return response to the user.
/Views	Views hold our UI templates
/Models	Models hold and manipulate data
/Content	This folder holds our images, CSS, and any other static content
/Scripts	This folder holds our JavaScript files

These folders are included even in an Empty ASP.NET MVC application because the ASP.NET MVC framework by default uses a "convention over configuration" approach and makes some default assumptions based on folder naming conventions. For instance, controllers look for views in the Views folder by default without you having to explicitly specify this in your code. Sticking with the default conventions reduces the amount of code you need to write, and can also make it easier for other developers to understand your project. We'll explain these conventions more as we build our application.

> This tutorial series details all of the steps taken to build the ASP.NET MVC Music Store sample application. Part 2 covers Controllers.

With traditional web frameworks, incoming URLs are typically mapped to files on disk. For example: a request for a URL like "/Products.aspx" or "/Products.php" might be processed by a "Products.aspx" or "Products.php" file.

Web-based MVC frameworks map URLs to server code in a slightly different way. Instead of mapping incoming URLs to files, they instead map URLs to methods on classes. These classes are called "Controllers" and they are responsible for processing incoming HTTP requests, handling user input, retrieving and saving data, and determining the response to send back to the client (display HTML, download a file, redirect to a different URL, etc.).

Adding a HomeController

We'll begin our MVC Music Store application by adding a Controller class that will handle URLs to the Home page of our site. We'll follow the default naming conventions of ASP.NET MVC and call it HomeController.

Right-click the "Controllers" folder within the Solution Explorer and select "Add", and then the "Controller..." command:

This will bring up the "Add Controller" dialog. Name the controller "HomeController" and press the Add button.

This will create a new file, HomeController.cs, with the following code:

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using System.Web.Mvc;

namespace MvcMusicStore.Controllers
{
    public class HomeController : Controller
    {
        //
        // GET: /Home/
        public ActionResult Index()
        {
            return View();
        }
    }
}
```

To start as simply as possible, let's replace the Index method with a simple method that just returns a string. We'll make two changes:

- Change the method to return a string instead of an ActionResult
- Change the return statement to return "Hello from Home"

The method should now look like this:

```
public string Index()
{
    return "Hello from Home";
}
```

Running the Application

Now let's run the site. We can start our web-server and try out the site using any of the following::

- Choose the Debug ⇨ Start Debugging menu item
- Click the Green arrow button in the toolbar

- Use the keyboard shortcut, F5.

Using any of the above steps will compile our project, and then cause the ASP.NET Development Server that is built-into Visual Web Developer to start. A notification will appear in the bottom corner of the screen to indicate that the ASP.NET Development Server has started up, and will show the port number that it is running under.

Visual Web Developer will then automatically open a browser window whose URL points to our web-server. This will allow us to quickly try out our web application:

Okay, that was pretty quick – we created a new website, added a three line function, and we've got text in a browser. Not rocket science, but it's a start.

Note: Visual Web Developer includes the ASP.NET Development Server, which will run your website on a random free "port" number. In the screenshot above, the site is running at `http://localhost:26641/`*, so it's using port 26641. Your port number will be different. When we talk about URL's like /Store/Browse in this tutorial, that will go after the port number. Assuming a port number of 26641, browsing to /Store/Browse will mean browsing to* `http://localhost:26641/Store/Browse`*.*

Adding a StoreController

We added a simple HomeController that implements the Home Page of our site. Let's now add another controller that we'll use to implement the browsing functionality of our music store. Our store controller will support three scenarios:

- A listing page of the music genres in our music store
- A browse page that lists all of the music albums in a particular genre
- A details page that shows information about a specific music album

We'll start by adding a new StoreController class.. If you haven't already, stop running the application either by closing the browser or selecting the Debug ⇨ Stop Debugging menu item.

Now add a new StoreController. Just like we did with HomeController, we'll do this by right-clicking on the "Controllers" folder within the Solution Explorer and choosing the Add->Controller menu item

Our new StoreController already has an "Index" method. We'll use this "Index" method to implement our listing page that lists all genres in our music store. We'll also add two additional methods to implement the two other scenarios we want our StoreController to handle: Browse and Details.

These methods (Index, Browse and Details) within our Controller are called "Controller Actions", and as you've already seen with the HomeController.Index()action method, their job is to respond to URL requests and (generally speaking) determine what content should be sent back to the browser or user that invoked the URL.

We'll start our StoreController implementation by changing theIndex() method to return the string "Hello from Store.Index()" and we'll add similar methods for Browse() and Details():

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using System.Web.Mvc;

namespace MvcMusicStore.Controllers
{
    public class StoreController : Controller
    {
        //
        // GET: /Store/
        public string Index()
        {
            return "Hello from Store.Index()";
        }
        //
        // GET: /Store/Browse
        public string Browse()
        {
            return "Hello from Store.Browse()";
        }
        //
        // GET: /Store/Details
        public string Details()
        {
            return "Hello from Store.Details()";
        }
    }
}
```

Run the project again and browse the following URLs:

- /Store
- /Store/Browse
- /Store/Details

Accessing these URLs will invoke the action methods within our Controller and return string responses:

That's great, but these are just constant strings. Let's make them dynamic, so they take information from the URL and display it in the page output.

First we'll change the Browse action method to retrieve a querystring value from the URL. We can do this by adding a "genre" parameter to our action method. When we do this ASP.NET MVC will automatically pass any querystring or form post parameters named "genre" to our action method when it is invoked.

```
//
// GET: /Store/Browse?genre=Disco
public string Browse(string genre)
 {
    string message = HttpUtility.HtmlEncode("Store.Browse, Genre = "
+ genre);

    return message;
 }
```

Note: We're using the HttpUtility.HtmlEncode utility method to sanitize the user input. This prevents users from injecting Javascript into our View with a link like /Store/Browse?Genre= <script>window.location='http://hackersite.com'</script>.

Now let's browse to /Store/Browse?Genre=Disco

Let's next change the Details action to read and display an input parameter named ID. Unlike our previous method, we won't be embedding the ID value as a querystring parameter. Instead we'll embed it directly within the URL itself. For example: /Store/Details/5.

ASP.NET MVC lets us easily do this without having to configure anything. ASP.NET MVC's default routing convention is to treat the segment of a URL after the action method name as a parameter named "ID". If your action method has a parameter named ID then ASP.NET MVC will automatically pass the URL segment to you as a parameter.

```
//
// GET: /Store/Details/5
public string Details(int id)
 {
    string message = "Store.Details, ID = " + id;

    return message;
 }
```

Run the application and browse to /Store/Details/5:

Let's recap what we've done so far:

- We've created a new ASP.NET MVC project in Visual Web Developer
- We've discussed the basic folder structure of an ASP.NET MVC application
- We've learned how to run our website using the ASP.NET Development Server
- We've created two Controller classes: a HomeController and a StoreController
- We've added Action Methods to our controllers which respond to URL requests and return text to the browser

Part 3: Views and ViewModels

So far we've just been returning strings from controller actions. That's a nice way to get an idea of how controllers work, but it's not how you'd want to build a real web application. We are going to want a better way to generate HTML back to browsers visiting our site – one where we can use template files to more easily customize the HTML content send back. That's exactly what Views do.

Adding a View template

To use a view-template, we'll change the HomeController Index method to return an ActionResult, and have it return View(), like below:

```
public class HomeController : Controller
{
    //
    // GET: /Home/
    public ActionResult Index()
    {
        return View();
    }
}
```

The above change indicates that instead of returned a string, we instead want to use a "View" to generate a result back.

We'll now add an appropriate View template to our project. To do this we'll position the text cursor within the Index action method, then right-click and select "Add View". This will bring up the Add View dialog:

The "Add View" dialog allows us to quickly and easily generate View template files. By default the "Add View" dialog pre-populates the name of the View template to create so that it matches the action method that will use it. Because we used the "Add View" context menu within the Index() action method of our HomeController, the "Add View" dialog above has "Index" as the view name pre-populated by default. We don't need to change any of the options on this dialog, so click the Add button.

When we click the Add button, Visual Web Developer will create a new Index.cshtml view template for us in the \Views\Home directory, creating the folder if doesn't already exist.

The name and folder location of the "Index.cshtml" file is important, and follows the default ASP.NET MVC naming conventions. The directory name, \Views\Home, matches the controller - which is named HomeController. The view template name, Index, matches the controller action method which will be displaying the view.

ASP.NET MVC allows us to avoid having to explicitly specify the name or location of a view template when we use this naming convention to return a view. It will by default render the \Views\Home\Index.cshtml view template when we write code like below within our HomeController:

```
public class HomeController : Controller
{
    //
    // GET: /Home/
    public ActionResult Index()
    {
        return View();
    }
}
```

Visual Web Developer created and opened the "Index.cshtml" view template after we clicked the "Add" button within the "Add View" dialog. The contents of Index.cshtml are shown below.

```
@{
    ViewBag.Title = "Index";
}
<h2>Index</h2>
```

This view is using the Razor syntax, which is more concise than the Web Forms view engine used in ASP.NET Web Forms and previous versions of ASP.NET MVC. The Web Forms view engine is still available in ASP.NET MVC 3, but many developers find that the Razor view engine fits ASP.NET MVC development really well.

The first three lines set the page title using ViewBag.Title. We'll look at how this works in more detail soon, but first let's update the text heading text and view the page. Update the <h2> tag to say "This is the Home Page" as shown below.

```
@{
    ViewBag.Title = "Index";
}
<h2>This is the Home Page</h2>
```

Running the application shows that our new text is visible on the home page.

Using a Layout for common site elements

Most websites have content which is shared between many pages: navigation, footers, logo images, stylesheet references, etc. The Razor view engine makes this easy to manage using a page called _Layout.cshtml which has automatically been created for us inside the /Views/Shared folder.

Double-click on this folder to view the contents, which are shown below.

```
<!DOCTYPE html>
<html>
<head>
    <meta charset="utf-8" />
    <title>@ViewBag.Title</title>
    <link href="@Url.Content("~/Content/Site.css")"
rel="stylesheet" type="text/css" />
    <script src="@Url.Content("~/Scripts/jquery-1.5.1.min.js")"
            type="text/javascript"></script>
    <script src="@Url.Content("~/Scripts/modernizr-1.7.min.js")"
            type="text/javascript"></script>
</head>
<body>
    @RenderBody()
</body>
</html>
```

The content from our individual views will be displayed by the @RenderBody() command, and any common content that we want to appear outside of that can be added to the _Layout.cshtml markup. We'll want our MVC Music Store to have a common header with links to our Home page and Store area on all pages in the site, so we'll add that to the template directly above that @RenderBody() statement.

```
<!DOCTYPE html>
<html>
<head>
    <title>@ViewBag.Title</title>
    <link href="@Url.Content("~/Content/Site.css")"
rel="stylesheet" type="text/css" />
    <script src="@Url.Content("~/Scripts/jquery-1.4.4.min.js")"
type="text/javascript"></script>
</head>
<body>
    <div id="header">
        <h1>
            ASP.NET MVC MUSIC STORE</h1>
        <ul id="navlist">
            <li class="first"><a href="/"
id="current">Home</a></li>
            <li><a
href="/Store/">Store</a></li>
        </ul>
    </div>
    @RenderBody()
</body>
</html>
```

Updating the StyleSheet

The empty project template includes a very streamlined CSS file which just includes styles used to display validation messages. Our designer has provided some additional CSS and images to define the look and feel for our site, so we'll add those in now.

The updated CSS file and Images are included in the Content directory of MvcMusicStore-Assets.zip which is available at MVC-Music-Store. We'll select both of them in Windows Explorer and drop them into our Solution's Content folder in Visual Web Developer, as shown below:

You'll be asked to confirm if you want to overwrite the existing Site.css file. Click Yes.

The Content folder of your application will now appear as follows:

Now let's run the application and see how our changes look on the Home page.

- Let's review what's changed: The HomeController's Index action method found and displayed the \Views\Home\Index.cshtmlView template, even though our code called "return View()", because our View template followed the standard naming convention.
- The Home Page is displaying a simple welcome message that is defined within the \Views\Home\Index.cshtml view template.
- The Home Page is using our _Layout.cshtml template, and so the welcome message is contained within the standard site HTML layout.

Using a Model to pass information to our View

A View template that just displays hardcoded HTML isn't going to make a very interesting web site. To create a dynamic web site, we'll instead want to pass information from our controller actions to our view templates.

In the Model-View-Controller pattern, the term Model refers to objects which represent the data in the application. Often, model objects correspond to tables in your database, but they don't have to.

Controller action methods which return an ActionResult can pass a model object to the view. This allows a Controller to cleanly package up all the information needed to generate a response, and then pass this information off to a View template to use to generate the appropriate HTML response. This is easiest to understand by seeing it

in action, so let's get started.

First we'll create some Model classes to represent Genres and Albums within our store. Let's start by creating a Genre class. Right-click the "Models" folder within your project, choose the "Add Class" option, and name the file "Genre.cs".

Then add a public string Name property to the class that was created:

```
public class Genre
{
    public string Name { get; set; }
}
```

Note: In case you're wondering, the { get; set; } notation is making use of C#'s auto-implemented properties feature. This gives us the benefits of a property without requiring us to declare a backing field.

Next, follow the same steps to create an Album class (named Album.cs) that has a Title and a Genre property:

```
public class Album
{
    public string Title { get; set; }
    public Genre Genre { get; set; }
}
```

Now we can modify the StoreController to use Views which display dynamic information from our Model. If - for

demonstration purposes right now - we named our Albums based on the request ID, we could display that information as in the view below.

We'll start by changing the Store Details action so it shows the information for a single album. Add a "using" statement to the top of the **StoreControllers** class to include the MvcMusicStore.Models namespace, so we don't need to type MvcMusicStore.Models.Album every time we want to use the album class. The "usings" section of that class should now appear as below.

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using System.Web.Mvc;
using MvcMusicStore.Models;
```

Next, we'll update the Details controller action so that it returns an ActionResult rather than a string, as we did with the HomeController's Index method.

```
public ActionResult Details(int id)
```

Now we can modify the logic to return an Album object to the view. Later in this tutorial we will be retrieving the data from a database – but for right now we will use "dummy data" to get started.

```
public ActionResult Details(int id)
 {
    var album = new Album { Title = "Album " + id };
    return View(album);
 }
```

Note: If you're unfamiliar with C#, you may assume that using var means that our album variable is late-bound. That's not correct – the C# compiler is using type-inference based on what we're assigning to the variable to determine that album is of type Album and compiling the local album variable as an Album type, so we get compile-time checking and Visual Studio code-editor support.

Let's now create a View template that uses our Album to generate an HTML response. Before we do that we need to build the project so that the Add View dialog knows about our newly created Album class. You can build the project by selecting the Debug⇨Build MvcMusicStore menu item (for extra credit, you can use the Ctrl-Shift-B shortcut to build the project).

Now that we've set up our supporting classes, we're ready to build our View template. Right-click within the Details method and select "Add View..." from the context menu.

We are going to create a new View template like we did before with the HomeController. Because we are creating it from the StoreController it will by default be generated in a \Views\Store\Index.cshtml file.

Unlike before, we are going to check the "Create a strongly-typed" view checkbox. We are then going to select our "Album" class within the "View data-class" drop-downlist. This will cause the "Add View" dialog to create a View template that expects that an Album object will be passed to it to use.

When we click the "Add" button our \Views\Store\Details.cshtml View template will be created, containing the following code.

```
@model MvcMusicStore.Models.Album
@{
    ViewBag.Title = "Details";
}
<h2>Details</h2>
```

Notice the first line, which indicates that this view is strongly-typed to our Album class. The Razor view engine understands that it has been passed an Album object, so we can easily access model properties and even have the benefit of IntelliSense in the Visual Web Developer editor.

Update the <h2> tag so it displays the Album's Title property by modifying that line to appear as follows.

```
<h2>Album: @Model.Title</h2>
```

Notice that IntelliSense is triggered when you enter the period after the @Model keyword, showing the properties and methods that the Album class supports.

Let's now re-run our project and visit the /Store/Details/5 URL. We'll see details of an Album like below.

Now we'll make a similar update for the Store Browse action method. Update the method so it returns an ActionResult, and modify the method logic so it creates a new Genre object and returns it to the View.

```
public ActionResult Browse(string genre)
 {
    var genreModel = new Genre { Name = genre };
    return View(genreModel);
 }
```

Right-click in the Browse method and select "Add View..." from the context menu, then add a View that is strongly-typed add a strongly typed to the Genre class.

Update the <h2> element in the view code (in /Views/Store/Browse.cshtml) to display the Genre information.

```
@model MvcMusicStore.Models.Genre
@{
    ViewBag.Title = "Browse";
}
<h2>Browsing Genre: @Model.Name</h2>
```

Now let's re-run our project and browse to the /Store/Browse?Genre=Disco URL. We'll see the Browse page displayed like below.

Finally, let's make a slightly more complex update to the **Store Index** action method and view to display a list of all the Genres in our store. We'll do that by using a List of Genres as our model object, rather than just a single Genre.

```
public ActionResult Index()
{
    var genres = new List<Genre>
    {
        new Genre { Name = "Disco"},
        new Genre { Name = "Jazz"},
        new Genre { Name = "Rock"}
    };
    return View(genres);
 }
```

Right-click in the Store Index action method and select Add View as before, select Genre as the Model class, and press the Add button.

First we'll change the @model declaration to indicate that the view will be expecting several Genre objects rather than just one. Change the first line of /Store/Index.cshtml to read as follows:

```
@model IEnumerable<MvcMusicStore.Models.Genre>
```

This tells the Razor view engine that it will be working with a model object that can hold several Genre objects. We're using an IEnumerable<Genre> rather than a List<Genre> since it's more generic, allowing us to change our model type later to any object type that supports the IEnumerable interface.

Next, we'll loop through the Genre objects in the model as shown in the completed view code below.

```
@model IEnumerable<MvcMusicStore.Models.Genre>
@{
    ViewBag.Title = "Store";
}
<h3>Browse Genres</h3>
<p>
    Select from @Model.Count()
genres:</p>
<ul>
    @foreach (var genre in Model)
    {
        <li>@genre.Name</li>
    }
</ul>
```

Notice that we have full IntelliSense support as we enter this code, so that when we type "@Model." we see all methods and properties supported by an IEnumerable of type Genre.

Within our "foreach" loop, Visual Web Developer knows that each item is of type Genre, so we see IntelliSense for each the Genre type.

Next, the scaffolding feature examined the Genre object and determined that each will have a Name property, so it loops through and writes them out. It also generates Edit, Details, and Delete links to each individual item. We'll take advantage of that later in our store manager, but for now we'd like to have a simple list instead.

When we run the application and browse to /Store, we see that both the count and list of Genres is displayed.

Adding Links between pages

Our /Store URL that lists Genres currently lists the Genre names simply as plain text. Let's change this so that instead of plain text we instead have the Genre names link to the appropriate /Store/Browse URL, so that clicking on a music genre like "Disco" will navigate to the /Store/Browse?genre=Disco URL. We could update our \Views\Store\Index.cshtml View template to output these links using code like below **(don't type this in - we're going to improve on it)**:

```
<ul>
    @foreach (var genre in Model)
    {
        <li><a href="/Store/Browse?genre=@genre.Name">@genre.Name</a></li>
    }
</ul>
```

That works, but it could lead to trouble later since it relies on a hardcoded string. For instance, if we wanted to rename the Controller, we'd need to search through our code looking for links that need to be updated.

An alternative approach we can use is to take advantage of an HTML Helper method. ASP.NET MVC includes HTML Helper methods which are available from our View template code to perform a variety of common tasks just like this. The Html.ActionLink() helper method is a particularly useful one, and makes it easy to build HTML <a> links and takes care of annoying details like making sure URL paths are properly URL encoded.

Html.ActionLink() has several different overloads to allow specifying as much information as you need for your links. In the simplest case, you'll supply just the link text and the Action method to go to when the hyperlink is clicked on the client. For example, we can link to "/Store/" Index() method on the Store Details page with the link text "Go to the Store Index" using the following call:

```
@Html.ActionLink("Go
to the Store Index", "Index")
```

Note: In this case, we didn't need to specify the controller name because we're just linking to another action within the same controller that's rendering the current view.

Our links to the Browse page will need to pass a parameter, though, so we'll use another overload of the

Html.ActionLink method that takes three parameters:

- 1. Link text, which will display the Genre name
- 2. Controller action name (Browse)
- 3. Route parameter values, specifying both the name (Genre) and the value (Genre name)

Putting that all together, here's how we'll write those links to the Store Index view:

```
<ul>
    @foreach (var genre in Model)
    {
        <li>@Html.ActionLink(genre.Name,
"Browse", new { genre = genre.Name })</li>
    }
</ul>
```

Now when we run our project again and access the /Store/ URL we will see a list of genres. Each genre is a hyperlink – when clicked it will take us to our /Store/Browse?genre=*[genre]* URL.

The HTML for the genre list looks like this:

```
<ul>
    <li><a href="/Store/Browse?genre=Disco">Disco</a>
</li>
    <li><a href="/Store/Browse?genre=Jazz">Jazz</a>
</li>
    <li><a href="/Store/Browse?genre=Rock">Rock</a>
</li>
</ul>
```

Part 4: Models and Data Access

2/20/2020 • 7 minutes to read • Edit Online

>
> This tutorial series details all of the steps taken to build the ASP.NET MVC Music Store sample application. Part 4 covers Models and Data Access.

So far, we've just been passing "dummy data" from our Controllers to our View templates. Now we're ready to hook up a real database. In this tutorial we'll be covering how to use SQL Server Compact Edition (often called SQL CE) as our database engine. SQL CE is a free, embedded, file based database that doesn't require any installation or configuration, which makes it really convenient for local development.

Database access with Entity Framework Code-First

We'll use the Entity Framework (EF) support that is included in ASP.NET MVC 3 projects to query and update the database. EF is a flexible object relational mapping (ORM) data API that enables developers to query and update data stored in a database in an object-oriented way.

Entity Framework version 4 supports a development paradigm called code-first. Code-first allows you to create model object by writing simple classes (also known as POCO from "plain-old" CLR objects), and can even create the database on the fly from your classes.

Changes to our Model Classes

We will be leveraging the database creation feature in Entity Framework in this tutorial. Before we do that, though, let's make a few minor changes to our model classes to add in some things we'll be using later on.

Adding the Artist Model Classes

Our Albums will be associated with Artists, so we'll add a simple model class to describe an Artist. Add a new class to the Models folder named Artist.cs using the code shown below.

```
namespace MvcMusicStore.Models
{
    public class Artist
    {
        public int ArtistId { get; set; }
        public string Name { get; set; }
    }
}
```

Updating our Model Classes

Update the Album class as shown below.

```
namespace MvcMusicStore.Models
{
    public class Album
    {
        public int      AlbumId     { get; set; }
        public int      GenreId     { get; set; }
        public int      ArtistId    { get; set; }
        public string   Title       { get; set; }
        public decimal  Price       { get; set; }
        public string   AlbumArtUrl { get; set; }
        public Genre    Genre       { get; set; }
        public Artist   Artist      { get; set; }
    }
}
```

Next, make the following updates to the Genre class.

```
using System.Collections.Generic;

namespace MvcMusicStore.Models
{
    public partial class Genre
    {
        public int      GenreId     { get; set; }
        public string   Name        { get; set; }
        public string   Description { get; set; }
        public List<Album> Albums   { get; set; }
    }
}
```

Adding the App_Data folder

We'll add an App_Data directory to our project to hold our SQL Server Express database files. App_Data is a special directory in ASP.NET which already has the correct security access permissions for database access. From the Project menu, select Add ASP.NET Folder, then App_Data.

Creating a Connection String in the web.config file

We will add a few lines to the website's configuration file so that Entity Framework knows how to connect to our database. Double-click on the Web.config file located in the root of the project.

Scroll to the bottom of this file and add a <connectionStrings> section directly above the last line, as shown below.

```
<connectionStrings>
    <add name="MusicStoreEntities"
     connectionString="Data Source=|DataDirectory|MvcMusicStore.sdf"
     providerName="System.Data.SqlServerCe.4.0"/>
  </connectionStrings>
</configuration>
```

Adding a Context Class

Right-click the Models folder and add a new class named MusicStoreEntities.cs.

This class will represent the Entity Framework database context, and will handle our create, read, update, and delete operations for us. The code for this class is shown below.

```
using System.Data.Entity;

namespace MvcMusicStore.Models
{
    public class MusicStoreEntities : DbContext
    {
        public DbSet<Album> Albums { get; set; }
        public DbSet<Genre> Genres { get; set; }
    }
}
```

That's it - there's no other configuration, special interfaces, etc. By extending the DbContext base class, our MusicStoreEntities class is able to handle our database operations for us. Now that we've got that hooked up, let's

add a few more properties to our model classes to take advantage of some of the additional information in our database.

Adding our store catalog data

We will take advantage of a feature in Entity Framework which adds "seed" data to a newly created database. This will pre-populate our store catalog with a list of Genres, Artists, and Albums. The MvcMusicStore-Assets.zip download - which included our site design files used earlier in this tutorial - has a class file with this seed data, located in a folder named Code.

Within the Code / Models folder, locate the SampleData.cs file and drop it into the Models folder in our project, as shown below.

Now we need to add one line of code to tell Entity Framework about that SampleData class. Double-click on the Global.asax file in the root of the project to open it and add the following line to the top the Application_Start method.

```
protected void Application_Start()
{
    System.Data.Entity.Database.SetInitializer(
    new MvcMusicStore.Models.SampleData());
    AreaRegistration.RegisterAllAreas();
    RegisterGlobalFilters(GlobalFilters.Filters);
    RegisterRoutes(RouteTable.Routes);
 }
```

At this point, we've completed the work necessary to configure Entity Framework for our project.

Querying the Database

Now let's update our StoreController so that instead of using "dummy data" it instead calls into our database to query all of its information. We'll start by declaring a field on the **StoreController** to hold an instance of the MusicStoreEntities class, named storeDB:

```
public class StoreController : Controller
{
    MusicStoreEntities storeDB = new MusicStoreEntities();
```

Updating the Store Index to query the database

The MusicStoreEntities class is maintained by the Entity Framework and exposes a collection property for each

table in our database. Let's update our StoreController's Index action to retrieve all Genres in our database. Previously we did this by hard-coding string data. Now we can instead just use the Entity Framework context Generes collection:

```
public ActionResult Index()
{
    var genres = storeDB.Genres.ToList();
    return View(genres);
 }
```

No changes need to happen to our View template since we're still returning the same StoreIndexViewModel we returned before - we're just returning live data from our database now.

When we run the project again and visit the "/Store" URL, we'll now see a list of all Genres in our database:

Updating Store Browse and Details to use live data

With the /Store/Browse?genre=*[some-genre]* action method, we're searching for a Genre by name. We only expect one result, since we shouldn't ever have two entries for the same Genre name, and so we can use the .Single() extension in LINQ to query for the appropriate Genre object like this (don't type this yet):

```
var example = storeDB.Genres.Single(g => g.Name == "Disco");
```

The Single method takes a Lambda expression as a parameter, which specifies that we want a single Genre object such that its name matches the value we've defined. In the case above, we are loading a single Genre object with a Name value matching Disco.

We'll take advantage of an Entity Framework feature that allows us to indicate other related entities we want loaded as well when the Genre object is retrieved. This feature is called Query Result Shaping, and enables us to reduce the number of times we need to access the database to retrieve all of the information we need. We want to pre-fetch the Albums for Genre we retrieve, so we'll update our query to include from Genres.Include("Albums") to indicate that we want related albums as well. This is more efficient, since it will retrieve both our Genre and Album data in a single database request.

With the explanations out of the way, here's how our updated Browse controller action looks:

```
public ActionResult Browse(string genre)
{
    // Retrieve Genre and its Associated Albums from database
    var genreModel = storeDB.Genres.Include("Albums")
        .Single(g => g.Name == genre);

    return View(genreModel);
}
```

We can now update the Store Browse View to display the albums which are available in each Genre. Open the view template (found in /Views/Store/Browse.cshtml) and add a bulleted list of Albums as shown below.

```
@model MvcMusicStore.Models.Genre
@{
    ViewBag.Title = "Browse";
}
<h2>Browsing Genre: @Model.Name</h2>
<ul>
    @foreach (var album in Model.Albums)
    {
        <li>
            @album.Title
        </li>
    }
</ul>
```

Running our application and browsing to /Store/Browse?genre=Jazz shows that our results are now being pulled from the database, displaying all albums in our selected Genre.

We'll make the same change to our /Store/Details/[id] URL, and replace our dummy data with a database query which loads an Album whose ID matches the parameter value.

```
public ActionResult Details(int id)
{
    var album = storeDB.Albums.Find(id);

    return View(album);
}
```

Running our application and browsing to /Store/Details/1 shows that our results are now being pulled from the database.

Now that our Store Details page is set up to display an album by the Album ID, let's update the **Browse** view to link to the Details view. We will use Html.ActionLink, exactly as we did to link from Store Index to Store Browse at the end of the previous section. The complete source for the Browse view appears below.

```
@model MvcMusicStore.Models.Genre
@{
    ViewBag.Title = "Browse";
}
<h2>Browsing Genre: @Model.Name</h2>
<ul>
    @foreach (var album in Model.Albums)
    {
        <li>
            @Html.ActionLink(album.Title,
"Details", new { id = album.AlbumId })
        </li>
    }
</ul>
```

We're now able to browse from our Store page to a Genre page, which lists the available albums, and by clicking on an album we can view details for that album.

Part 5: Edit Forms and Templating

2/20/2020 • 15 minutes to read • Edit Online

by Jon Galloway

The MVC Music Store is a tutorial application that introduces and explains step-by-step how to use ASP.NET MVC and Visual Studio for web development.

The MVC Music Store is a lightweight sample store implementation which sells music albums online, and implements basic site administration, user sign-in, and shopping cart functionality.

This tutorial series details all of the steps taken to build the ASP.NET MVC Music Store sample application. Part 5 covers Edit Forms and Templating.

In the past chapter, we were loading data from our database and displaying it. In this chapter, we'll also enable editing the data.

Creating the StoreManagerController

We'll begin by creating a new controller called **StoreManagerController**. For this controller, we will be taking advantage of the Scaffolding features available in the ASP.NET MVC 3 Tools Update. Set the options for the Add Controller dialog as shown below.

When you click the Add button, you'll see that the ASP.NET MVC 3 scaffolding mechanism does a good amount of work for you:

- It creates the new StoreManagerController with a local Entity Framework variable
- It adds a StoreManager folder to the project's Views folder
- It adds Create.cshtml, Delete.cshtml, Details.cshtml, Edit.cshtml, and Index.cshtml view, strongly typed to the Album class

The new StoreManager controller class includes CRUD (create, read, update, delete) controller actions which know how to work with the Album model class and use our Entity Framework context for database access.

Modifying a Scaffolded View

It's important to remember that, while this code was generated for us, it's standard ASP.NET MVC code, just like we've been writing throughout this tutorial. It's intended to save you the time you'd spend on writing boilerplate controller code and creating the strongly typed views manually, but this isn't the kind of generated code you may have seen prefaced with dire warnings in comments about how you mustn't change the code. This is your code, and you're expected to change it.

So, let's start with a quick edit to the StoreManager Index view (/Views/StoreManager/Index.cshtml). This view will display a table which lists the Albums in our store with Edit / Details / Delete links, and includes the Album's public properties. We'll remove the AlbumArtUrl field, as it's not very useful in this display. In <table> section of the view code, remove the <th> and <td> elements surrounding AlbumArtUrl references, as indicated by the highlighted lines below:

```
<table>
    <tr>
        <th>
            Genre
        </th>
        <th>
            Artist
        </th>
        <th>
            Title
        </th>
        <th>
            Price
        </th>
        <th>
            AlbumArtUrl
        </th>
        <th></th>
    </tr>
@foreach (var item in Model) {
    <tr>
        <td>
            @Html.DisplayFor(modelItem => item.Genre.Name)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Artist.Name)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Title)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Price)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.AlbumArtUrl)
        </td>
        <td>
            @Html.ActionLink("Edit", "Edit", new { id=item.AlbumId }) |
            @Html.ActionLink("Details", "Details", new { id=item.AlbumId }) |
            @Html.ActionLink("Delete", "Delete", new { id=item.AlbumId })
        </td>
    </tr>
}
</table>
```

The modified view code will appear as follows:

```
@model IEnumerable<MvcMusicStore.Models.Album>
@{
    ViewBag.Title = "Index";
}
<h2>Index</h2>
<p>
    @Html.ActionLink("Create
New", "Create")
</p>
<table>
    <tr>
        <th>
            Genre
        </th>
        <th>
            Artist
        </th>
        <th>
            Title
        </th>
        <th>
            Price
        </th>
        <th></th>
    </tr>
@foreach (var item in Model) {
    <tr>
        <td>
            @Html.DisplayFor(modelItem => item.Genre.Name)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Artist.Name)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Title)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Price)
        </td>
        <td>
            @Html.ActionLink("Edit", "Edit", new { id=item.AlbumId }) |
            @Html.ActionLink("Details", "Details", new { id=item.AlbumId }) |
            @Html.ActionLink("Delete", "Delete", new { id=item.AlbumId })
        </td>
    </tr>
}
</table>
```

A first look at the Store Manager

Now run the application and browse to /StoreManager/. This displays the Store Manager Index we just modified, showing a list of the albums in the store with links to Edit, Details, and Delete.

Clicking the Edit link displays an edit form with fields for the Album, including dropdowns for Genre and Artist.

Click the "Back to List" link at the bottom, then click on the Details link for an Album. This displays the detail information for an individual Album.

Again, click the Back to List link, then click on a Delete link. This displays a confirmation dialog, showing the album details and asking if we're sure we want to delete it.

Clicking the Delete button at the bottom will delete the album and return you to the Index page, which shows the album deleted.

We're not done with the Store Manager, but we have working controller and view code for the CRUD operations to start from.

Looking at the Store Manager Controller code

The Store Manager Controller contains a good amount of code. Let's go through this from top to bottom. The controller includes some standard namespaces for an MVC controller, as well as a reference to our Models namespace. The controller has a private instance of MusicStoreEntities, used by each of the controller actions for data access.

```
using System;
using System.Collections.Generic;
using System.Data;
using System.Data.Entity;
using System.Linq;
using System.Web;
using System.Web.Mvc;
using MvcMusicStore.Models;

namespace MvcMusicStore.Controllers
{
    public class StoreManagerController : Controller
    {
        private MusicStoreEntities db = new MusicStoreEntities();
```

Store Manager Index and Details actions

The index view retrieves a list of Albums, including each album's referenced Genre and Artist information, as we previously saw when working on the Store Browse method. The Index view is following the references to the linked objects so that it can display each album's Genre name and Artist name, so the controller is being efficient and querying for this information in the original request.

```
//
// GET: /StoreManager/
public ViewResult Index()
{
    var albums = db.Albums.Include(a => a.Genre).Include(a => a.Artist);
    return View(albums.ToList());
}
```

The StoreManager Controller's Details controller action works exactly the same as the Store Controller Details action we wrote previously - it queries for the Album by ID using the Find() method, then returns it to the view.

```
//
// GET: /StoreManager/Details/5
public ViewResult Details(int id)
{
    Album album = db.Albums.Find(id);
    return View(album);
}
```

The Create Action Methods

The Create action methods are a little different from ones we've seen so far, because they handle form input. When a user first visits /StoreManager/Create/ they will be shown an empty form. This HTML page will contain a <form> element that contains dropdown and textbox input elements where they can enter the album's details.

After the user fills in the Album form values, they can press the "Save" button to submit these changes back to our application to save within the database. When the user presses the "save" button the <form> will perform an HTTP-POST back to the /StoreManager/Create/ URL and submit the <form> values as part of the HTTP-POST.

ASP.NET MVC allows us to easily split up the logic of these two URL invocation scenarios by enabling us to implement two separate "Create" action methods within our StoreManagerController class – one to handle the initial HTTP-GET browse to the /StoreManager/Create/ URL, and the other to handle the HTTP-POST of the submitted changes.

Passing information to a View using ViewBag

We've used the ViewBag earlier in this tutorial, but haven't talked much about it. The ViewBag allows us to pass information to the view without using a strongly typed model object. In this case, our Edit HTTP-GET controller

action needs to pass both a list of Genres and Artists to the form to populate the dropdowns, and the simplest way to do that is to return them as ViewBag items.

The ViewBag is a dynamic object, meaning that you can type ViewBag.Foo or ViewBag.YourNameHere without writing code to define those properties. In this case, the controller code uses ViewBag.GenreId and ViewBag.ArtistId so that the dropdown values submitted with the form will be GenreId and ArtistId, which are the Album properties they will be setting.

These dropdown values are returned to the form using the SelectList object, which is built just for that purpose. This is done using code like this:

```
ViewBag.GenreId = new SelectList(db.Genres, "GenreId", "Name");
```

As you can see from the action method code, three parameters are being used to create this object:

- The list of items the dropdown will be displaying. Note that this isn't just a string - we're passing a list of Genres.
- The next parameter being passed to the SelectList is the Selected Value. This how the SelectList knows how to pre-select an item in the list. This will be easier to understand when we look at the Edit form, which is pretty similar.
- The final parameter is the property to be displayed. In this case, this is indicating that the Genre.Name property is what will be shown to the user.

With that in mind, then, the HTTP-GET Create action is pretty simple - two SelectLists are added to the ViewBag, and no model object is passed to the form (since it hasn't been created yet).

```
//
// GET: /StoreManager/Create
public ActionResult Create()
{
    ViewBag.GenreId = new SelectList(db.Genres, "GenreId", "Name");
    ViewBag.ArtistId = new SelectList(db.Artists, "ArtistId", "Name");
    return View();
}
```

HTML Helpers to display the Drop Downs in the Create View

Since we've talked about how the drop down values are passed to the view, let's take a quick look at the view to see how those values are displayed. In the view code (/Views/StoreManager/Create.cshtml), you'll see the following call is made to display the Genre drop down.

```
@Html.DropDownList("GenreId",
String.Empty)
```

This is known as an HTML Helper - a utility method which performs a common view task. HTML Helpers are very useful in keeping our view code concise and readable. The Html.DropDownList helper is provided by ASP.NET MVC, but as we'll see later it's possible to create our own helpers for view code we'll reuse in our application.

The Html.DropDownList call just needs to be told two things - where to get the list to display, and what value (if any) should be pre-selected. The first parameter, GenreId, tells the DropDownList to look for a value named GenreId in either the model or ViewBag. The second parameter is used to indicate the value to show as initially selected in the drop down list. Since this form is a Create form, there's no value to be preselected and String.Empty is passed.

Handling the Posted Form values

As we discussed before, there are two action methods associated with each form. The first handles the HTTP-GET

request and displays the form. The second handles the HTTP-POST request, which contains the submitted form values. Notice that controller action has an [HttpPost] attribute, which tells ASP.NET MVC that it should only respond to HTTP-POST requests.

```
//
// POST: /StoreManager/Create
[HttpPost]
public ActionResult Create(Album album)
{
    if (ModelState.IsValid)
    {
        db.Albums.Add(album);
        db.SaveChanges();
        return RedirectToAction("Index");
    }
    ViewBag.GenreId = new SelectList(db.Genres, "GenreId", "Name", album.GenreId);
    ViewBag.ArtistId = new SelectList(db.Artists, "ArtistId", "Name", album.ArtistId);
    return View(album);
}
```

This action has four responsibilities:

- 1. Read the form values
- 2. Check if the form values pass any validation rules
- 3. If the form submission is valid, save the data and display the updated list
- 4. If the form submission is not valid, redisplay the form with validation errors

Reading Form Values with Model Binding

The controller action is processing a form submission that includes values for GenreId and ArtistId (from the drop down list) and textbox values for Title, Price, and AlbumArtUrl. While it's possible to directly access form values, a better approach is to use the Model Binding capabilities built into ASP.NET MVC. When a controller action takes a model type as a parameter, ASP.NET MVC will attempt to populate an object of that type using form inputs (as well as route and querystring values). It does this by looking for values whose names match properties of the model object, e.g. when setting the new Album object's GenreId value, it looks for an input with the name GenreId. When you create views using the standard methods in ASP.NET MVC, the forms will always be rendered using property names as input field names, so this the field names will just match up.

Validating the Model

The model is validated with a simple call to ModelState.IsValid. We haven't added any validation rules to our Album class yet - we'll do that in a bit - so right now this check doesn't have much to do. What's important is that this ModelStat.IsValid check will adapt to the validation rules we put on our model, so future changes to validation rules won't require any updates to the controller action code.

Saving the submitted values

If the form submission passes validation, it's time to save the values to the database. With Entity Framework, that just requires adding the model to the Albums collection and calling SaveChanges.

```
db.Albums.Add(album);
db.SaveChanges();
```

Entity Framework generates the appropriate SQL commands to persist the value. After saving the data, we redirect back to the list of Albums so we can see our update. This is done by returning RedirectToAction with the name of the controller action we want displayed. In this case, that's the Index method.

Displaying invalid form submissions with Validation Errors

In the case of invalid form input, the dropdown values are added to the ViewBag (as in the HTTP-GET case) and the bound model values are passed back to the view for display. Validation errors are automatically displayed using

the @Html.ValidationMessageFor HTML Helper.

Testing the Create Form

To test this out, run the application and browse to /StoreManager/Create/ - this will show you the blank form which was returned by the StoreController Create HTTP-GET method.

Fill in some values and click the Create button to submit the form.

Jazz	Miles Davis	Miles Ahead	8.99	Edit | Details | Delete
Jazz	Miles Davis	The Essential Miles Davis [Disc 1]	8.99	Edit | Details | Delete
Jazz	Miles Davis	The Essential Miles Davis [Disc 2]	8.99	Edit | Details | Delete
Jazz	Spyro Gyra	Heart of the Night	8.99	Edit | Details | Delete
Jazz	Spyro Gyra	Morning Dance	8.99	Edit | Details | Delete
Pop	Donna Summer	Jon Galloway and Donna Summer Sing!	50.00	Edit | Details | Delete
Pop	Amy Winehouse	Frank	8.99	Edit | Details | Delete

Handling Edits

The Edit action pair (HTTP-GET and HTTP-POST) are very similar to the Create action methods we just looked at. Since the edit scenario involves working with an existing album, the Edit HTTP-GET method loads the Album based on the "id" parameter, passed in via the route. This code for retrieving an album by AlbumId is the same as we've previously looked at in the Details controller action. As with the Create / HTTP-GET method, the drop down values are returned via the ViewBag. This allows us to return an Album as our model object to the view (which is strongly typed to the Album class) while passing additional data (e.g. a list of Genres) via the ViewBag.

```
//
// GET: /StoreManager/Edit/5
public ActionResult Edit(int id)
{
    Album album = db.Albums.Find(id);
    ViewBag.GenreId = new SelectList(db.Genres, "GenreId", "Name", album.GenreId);
    ViewBag.ArtistId = new SelectList(db.Artists, "ArtistId", "Name", album.ArtistId);
    return View(album);
}
```

The Edit HTTP-POST action is very similar to the Create HTTP-POST action. The only difference is that instead of adding a new album to the db.Albums collection, we're finding the current instance of the Album using db.Entry(album) and setting its state to Modified. This tells Entity Framework that we are modifying an existing album as opposed to creating a new one.

```
//
// POST: /StoreManager/Edit/5
[HttpPost]
public ActionResult Edit(Album album)
{
    if (ModelState.IsValid)
    {
        db.Entry(album).State = EntityState.Modified;
        db.SaveChanges();
        return RedirectToAction("Index");
    }
    ViewBag.GenreId = new SelectList(db.Genres, "GenreId", "Name", album.GenreId);
    ViewBag.ArtistId = new SelectList(db.Artists, "ArtistId", "Name", album.ArtistId);
    return View(album);
}
```

We can test this out by running the application and browsing to /StoreManger/, then clicking the Edit link for an album.

Genre	Artist	Title	Price	
Rock	Men At Work	The Best Of Men At Work	8.99	Edit | Details | Delete
Rock	AC/DC	For Those About To Rock We Salute You	8.99	Edit | Details | Delete
Rock	AC/DC	Let There Be Rock	8.99	Edit | Details | Delete
Rock	Accept	Balls to the Wall	8.99	Edit | Details | Delete
Rock	Accept	Restless and Wild	8.99	Edit | Details | Delete
Rock	Aerosmith	Big Ones	8.99	Edit | Details | Delete

This displays the Edit form shown by the Edit HTTP-GET method. Fill in some values and click the Save button.

This posts the form, saves the values, and returns us to the Album list, showing that the values were updated.

Jazz	Spyro Gyra	Heart of the Night	8.99	Edit | Details | Delete
Jazz	Spyro Gyra	Morning Dance	8.99	Edit | Details | Delete
Pop	Amy Winehouse	Frank	8.99	Edit | Details | Delete
Pop	Various Artists	Axé Bahia 2001	8.99	Edit | Details | Delete
Disco	Men At Work	The Worst Of Men At Work	10.99	Edit | Details | Delete
Disco	Anita Ward	Ring My Bell	8.99	Edit | Details | Delete

Handling Deletion

Deletion follows the same pattern as Edit and Create, using one controller action to display the confirmation form, and another controller action to handle the form submission.

The HTTP-GET Delete controller action is exactly the same as our previous Store Manager Details controller action.

```
//
// GET: /StoreManager/Delete/5

public ActionResult Delete(int id)
{
    Album album = db.Albums.Find(id);
    return View(album);
}
```

We display a form that's strongly typed to an Album type, using the Delete view content template.

The Delete template shows all the fields for the model, but we can simplify that down quite a bit. Change the view code in /Views/StoreManager/Delete.cshtml to the following.

```
@model MvcMusicStore.Models.Album
@{
    ViewBag.Title = "Delete";
}
<h2>Delete Confirmation</h2>
<p>Are you sure you want to delete the album titled
   <strong>@Model.Title</strong>?
</p>
@using (Html.BeginForm()) {
    <p>
        <input type="submit" value="Delete" />
    </p>
    <p>
        @Html.ActionLink("Back to
List", "Index")
    </p>
}
```

This displays a simplified Delete confirmation.

Clicking the Delete button causes the form to be posted back to the server, which executes the DeleteConfirmed action.

```
//
// POST: /StoreManager/Delete/5
[HttpPost, ActionName("Delete")]
public ActionResult DeleteConfirmed(int id)
{
    Album album = db.Albums.Find(id);
    db.Albums.Remove(album);
    db.SaveChanges();
    return RedirectToAction("Index");
}
```

Our HTTP-POST Delete Controller Action takes the following actions:

- 1. Loads the Album by ID
- 2. Deletes it the album and save changes
- 3. Redirects to the Index, showing that the Album was removed from the list

To test this, run the application and browse to /StoreManager. Select an album from the list and click the Delete link.

This displays our Delete confirmation screen.

Clicking the Delete button removes the album and returns us to the Store Manager Index page, which shows that the album has been deleted.

Using a custom HTML Helper to truncate text

We've got one potential issue with our Store Manager Index page. Our Album Title and Artist Name properties can both be long enough that they could throw off our table formatting. We'll create a custom HTML Helper to allow us to easily truncate these and other properties in our Views.

Razor's @helper syntax has made it pretty easy to create your own helper functions for use in your views. Open the /Views/StoreManager/Index.cshtml view and add the following code directly after the @model line.

```
@helper Truncate(string
input, int length)
 {
    if (input.Length <= length) {
        @input
    } else {
        @input.Substring(0, length)<text>...</text>
    }
}
```

This helper method takes a string and a maximum length to allow. If the text supplied is shorter than the length specified, the helper outputs it as-is. If it is longer, then it truncates the text and renders "..." for the remainder.

Now we can use our Truncate helper to ensure that both the Album Title and Artist Name properties are less than 25 characters. The complete view code using our new Truncate helper appears below.

```
@model IEnumerable<MvcMusicStore.Models.Album>
@helper Truncate(string input, int length)
 {
    if (input.Length <= length) {
        @input
    } else {
        @input.Substring(0, length)<text>...</text>
    }
}
@{
    ViewBag.Title = "Index";
}
<h2>Index</h2>
<p>
    @Html.ActionLink("Create
New", "Create")
</p>
<table>
    <tr>
        <th>
            Genre
        </th>
        <th>
            Artist
        </th>
        <th>
            Title
        </th>
        <th>
            Price
        </th>
        <th></th>
    </tr>
@foreach (var item in Model) {
    <tr>
        <td>
            @Html.DisplayFor(modelItem => item.Genre.Name)
        </td>
        <td>
            @Truncate(item.Artist.Name, 25)
        </td>
        <td>
            @Truncate(item.Title, 25)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Price)
        </td>
        <td>
            @Html.ActionLink("Edit", "Edit", new { id=item.AlbumId }) |
            @Html.ActionLink("Details", "Details", new { id=item.AlbumId }) |
            @Html.ActionLink("Delete", "Delete", new { id=item.AlbumId })
        </td>
    </tr>
}
</table>
```

Now when we browse the /StoreManager/ URL, the albums and titles are kept below our maximum lengths.

Note: This shows the simple case of creating and using a helper in one view. To learn more about creating helpers that you can use throughout your site, see my blog post: http://bit.ly/mvc3-helper-options

Part 6: Using Data Annotations for Model Validation

9/16/2020 • 3 minutes to read • Edit Online

by Jon Galloway

> The MVC Music Store is a tutorial application that introduces and explains step-by-step how to use ASP.NET MVC and Visual Studio for web development.
>
> The MVC Music Store is a lightweight sample store implementation which sells music albums online, and implements basic site administration, user sign-in, and shopping cart functionality.
>
> This tutorial series details all of the steps taken to build the ASP.NET MVC Music Store sample application. Part 6 covers Using Data Annotations for Model Validation.

We have a major issue with our Create and Edit forms: they're not doing any validation. We can do things like leave required fields blank or type letters in the Price field, and the first error we'll see is from the database.

We can easily add validation to our application by adding Data Annotations to our model classes. Data Annotations allow us to describe the rules we want applied to our model properties, and ASP.NET MVC will take care of enforcing them and displaying appropriate messages to our users.

Adding Validation to our Album Forms

We'll use the following Data Annotation attributes:

- **Required** – Indicates that the property is a required field
- **DisplayName** – Defines the text to use on form fields and validation messages
- **StringLength** – Defines a maximum length for a string field
- **Range** – Gives a maximum and minimum value for a numeric field
- **Bind** – Lists fields to exclude or include when binding parameter or form values to model properties
- **ScaffoldColumn** – Allows hiding fields from editor forms

Note: For more information on Model Validation using Data Annotation attributes, see the MSDN documentation at `https://go.microsoft.com/fwlink/?LinkId=159063`

Open the Album class and add the following *using* statements to the top.

```
using System.ComponentModel;
using System.ComponentModel.DataAnnotations;
using System.Web.Mvc;
```

Next, update the properties to add display and validation attributes as shown below.

```
namespace MvcMusicStore.Models
{
    [Bind(Exclude = "AlbumId")]
    public class Album
    {
        [ScaffoldColumn(false)]
        public int      AlbumId    { get; set; }
        [DisplayName("Genre")]
        public int      GenreId    { get; set; }
        [DisplayName("Artist")]
        public int      ArtistId   { get; set; }
        [Required(ErrorMessage = "An Album Title is required")]
        [StringLength(160)]
        public string   Title      { get; set; }
        [Range(0.01, 100.00,
            ErrorMessage = "Price must be between 0.01 and 100.00")]
        public decimal Price       { get; set; }
        [DisplayName("Album Art URL")]
        [StringLength(1024)]
        public string AlbumArtUrl { get; set; }
        public virtual Genre  Genre    { get; set; }
        public virtual Artist Artist   { get; set; }
    }
}
```

While we're there, we've also changed the Genre and Artist to virtual properties. This allows Entity Framework to lazy-load them as necessary.

```
public virtual Genre    Genre       { get; set; }
public virtual Artist   Artist      { get; set; }
```

After having added these attributes to our Album model, our Create and Edit screen immediately begin validating fields and using the Display Names we've chosen (e.g. Album Art Url instead of AlbumArtUrl). Run the application and browse to /StoreManager/Create.

Next, we'll break some validation rules. Enter a price of 0 and leave the Title blank. When we click on the Create button, we will see the form displayed with validation error messages showing which fields did not meet the validation rules we have defined.

Testing the Client-Side Validation

Server-side validation is very important from an application perspective, because users can circumvent client-side validation. However, webpage forms which only implement server-side validation exhibit three significant problems.

1. The user has to wait for the form to be posted, validated on the server, and for the response to be sent to their browser.
2. The user doesn't get immediate feedback when they correct a field so that it now passes the validation rules.
3. We are wasting server resources to perform validation logic instead of leveraging the user's browser.

Fortunately, the ASP.NET MVC 3 scaffold templates have client-side validation built in, requiring no additional work whatsoever.

Typing a single letter in the Title field satisfies the validation requirements, so the validation message is immediately removed.

Part 7: Membership and Authorization

2/20/2020 • 2 minutes to read • Edit Online

by Jon Galloway

> The MVC Music Store is a tutorial application that introduces and explains step-by-step how to use ASP.NET MVC and Visual Studio for web development.

>
> This tutorial series details all of the steps taken to build the ASP.NET MVC Music Store sample application. Part 7 covers Membership and Authorization.

Our Store Manager controller is currently accessible to anyone visiting our site. Let's change this to restrict permission to site administrators.

Adding the AccountController and Views

One difference between the full ASP.NET MVC 3 Web Application template and the ASP.NET MVC 3 Empty Web Application template is that the empty template doesn't include an Account Controller. We'll add an Account Controller by copying a few files from a new ASP.NET MVC application created from the full ASP.NET MVC 3 Web Application template.

Create a new ASP.NET MVC application using the full ASP.NET MVC 3 Web Application template and copy the following files into the same directories in our project:

1. Copy AccountController.cs in the Controllers directory
2. Copy AccountModels in the Models directory
3. Create an Account directory inside the Views directory and copy all four views in

Change the namespace for the Controller and Model classes so they begin with MvcMusicStore. The AccountController class should use the MvcMusicStore.Controllers namespace, and the AccountModels class should use the MvcMusicStore.Models namespace.

Note: These files are also available in the MvcMusicStore-Assets.zip download from which we copied our site design files at the beginning of the tutorial. The Membership files are located in the Code directory.

The updated solution should look like the following:

Adding an Administrative User with the ASP.NET Configuration site

Before we require Authorization in our website, we'll need to create a user with access. The easiest way to create a user is to use the built-in ASP.NET Configuration website.

Launch the ASP.NET Configuration website by clicking following the icon in the Solution Explorer.

This launches a configuration website. Click on the Security tab on the home screen, then click the "Enable roles" link in the center of the screen.

Click the "Create or Manage roles" link.

Enter "Administrator" as the role name and press the Add Role button.

Click the Back button, then click on the Create user link on the left side.

Fill in the user information fields on the left using the following information:

FIELD	VALUE
User Name	Administrator
Password	password123!
Confirm Password	password123!
E-mail	(any email address will work)
Security Question	(whatever you like)
Security Answer	(whatever you like)

Note: You can of course use any password you'd like. The default password security settings require a password that is 7 characters long and contains one non-alphanumeric character.

Select the Administrator role for this user, and click the Create User button.

At this point, you should see a message indicating that the user was created successfully.

You can now close the browser window.

Role-based Authorization

Now we can restrict access to the StoreManagerController using the [Authorize] attribute, specifying that the user must be in the Administrator role to access any controller action in the class.

```
[Authorize(Roles = "Administrator")]
public class StoreManagerController : Controller
{
    // Controller code here
}
```

Note: The [Authorize] attribute can be placed on specific action methods as well as at the Controller class level.

Now browsing to /StoreManager brings up a Log On dialog:

After logging on with our new Administrator account, we're able to go to the Album Edit screen as before.

Part 8: Shopping Cart with Ajax Updates

2/20/2020 • 13 minutes to read • Edit Online

by Jon Galloway

> The MVC Music Store is a tutorial application that introduces and explains step-by-step how to use ASP.NET MVC and Visual Studio for web development.
>
> The MVC Music Store is a lightweight sample store implementation which sells music albums online, and implements basic site administration, user sign-in, and shopping cart functionality.
>
> This tutorial series details all of the steps taken to build the ASP.NET MVC Music Store sample application. Part 8 covers Shopping Cart with Ajax Updates.

We'll allow users to place albums in their cart without registering, but they'll need to register as guests to complete checkout. The shopping and checkout process will be separated into two controllers: a ShoppingCart Controller which allows anonymously adding items to a cart, and a Checkout Controller which handles the checkout process. We'll start with the Shopping Cart in this section, then build the Checkout process in the following section.

Adding the Cart, Order, and OrderDetail model classes

Our Shopping Cart and Checkout processes will make use of some new classes. Right-click the Models folder and add a Cart class (Cart.cs) with the following code.

```
using System.ComponentModel.DataAnnotations;

namespace MvcMusicStore.Models
{
    public class Cart
    {
        [Key]
        public int      RecordId    { get; set; }
        public string   CartId      { get; set; }
        public int      AlbumId     { get; set; }
        public int      Count       { get; set; }
        public System.DateTime DateCreated { get; set; }
        public virtual Album Album  { get; set; }
    }
}
```

This class is pretty similar to others we've used so far, with the exception of the [Key] attribute for the RecordId property. Our Cart items will have a string identifier named CartID to allow anonymous shopping, but the table includes an integer primary key named RecordId. By convention, Entity Framework Code-First expects that the primary key for a table named Cart will be either CartId or ID, but we can easily override that via annotations or code if we want. This is an example of how we can use the simple conventions in Entity Framework Code-First when they suit us, but we're not constrained by them when they don't.

Next, add an Order class (Order.cs) with the following code.

```
using System.Collections.Generic;

namespace MvcMusicStore.Models
{
    public partial class Order
    {
        public int    OrderId    { get; set; }
        public string Username   { get; set; }
        public string FirstName  { get; set; }
        public string LastName   { get; set; }
        public string Address    { get; set; }
        public string City       { get; set; }
        public string State      { get; set; }
        public string PostalCode { get; set; }
        public string Country    { get; set; }
        public string Phone      { get; set; }
        public string Email      { get; set; }
        public decimal Total     { get; set; }
        public System.DateTime OrderDate      { get; set; }
        public List<OrderDetail> OrderDetails { get; set; }
    }
}
```

This class tracks summary and delivery information for an order. **It won't compile yet**, because it has an OrderDetails navigation property which depends on a class we haven't created yet. Let's fix that now by adding a class named OrderDetail.cs, adding the following code.

```
namespace MvcMusicStore.Models
{
    public class OrderDetail
    {
        public int OrderDetailId { get; set; }
        public int OrderId { get; set; }
        public int AlbumId { get; set; }
        public int Quantity { get; set; }
        public decimal UnitPrice { get; set; }
        public virtual Album Album { get; set; }
        public virtual Order Order { get; set; }
    }
}
```

We'll make one last update to our MusicStoreEntities class to include DbSets which expose those new Model classes, also including a DbSet<Artist>. The updated MusicStoreEntities class appears as below.

```
using System.Data.Entity;

namespace MvcMusicStore.Models
{
    public class MusicStoreEntities : DbContext
    {
        public DbSet<Album>     Albums  { get; set; }
        public DbSet<Genre>     Genres  { get; set; }
        public DbSet<Artist>    Artists {
get; set; }
        public DbSet<Cart>
Carts { get; set; }
        public DbSet<Order>     Orders
{ get; set; }
        public DbSet<OrderDetail>
OrderDetails { get; set; }
    }
}
```

Managing the Shopping Cart business logic

Next, we'll create the ShoppingCart class in the Models folder. The ShoppingCart model handles data access to the Cart table. Additionally, it will handle the business logic to for adding and removing items from the shopping cart.

Since we don't want to require users to sign up for an account just to add items to their shopping cart, we will assign users a temporary unique identifier (using a GUID, or globally unique identifier) when they access the shopping cart. We'll store this ID using the ASP.NET Session class.

Note: The ASP.NET Session is a convenient place to store user-specific information which will expire after they leave the site. While misuse of session state can have performance implications on larger sites, our light use will work well for demonstration purposes.

The ShoppingCart class exposes the following methods:

AddToCart takes an Album as a parameter and adds it to the user's cart. Since the Cart table tracks quantity for each album, it includes logic to create a new row if needed or just increment the quantity if the user has already ordered one copy of the album.

RemoveFromCart takes an Album ID and removes it from the user's cart. If the user only had one copy of the album in their cart, the row is removed.

EmptyCart removes all items from a user's shopping cart.

GetCartItems retrieves a list of CartItems for display or processing.

GetCount retrieves a the total number of albums a user has in their shopping cart.

GetTotal calculates the total cost of all items in the cart.

CreateOrder converts the shopping cart to an order during the checkout phase.

GetCart is a static method which allows our controllers to obtain a cart object. It uses the **GetCartId** method to handle reading the CartId from the user's session. The GetCartId method requires the HttpContextBase so that it can read the user's CartId from user's session.

Here's the complete **ShoppingCart class**:

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using System.Web.Mvc;

namespace MvcMusicStore.Models
{
    public partial class ShoppingCart
    {
        MusicStoreEntities storeDB = new MusicStoreEntities();
        string ShoppingCartId { get; set; }
        public const string CartSessionKey = "CartId";
        public static ShoppingCart GetCart(HttpContextBase context)
        {
            var cart = new ShoppingCart();
            cart.ShoppingCartId = cart.GetCartId(context);
            return cart;
        }
        // Helper method to simplify shopping cart calls
        public static ShoppingCart GetCart(Controller controller)
        {
            return GetCart(controller.HttpContext);
        }
        public void AddToCart(Album album)
        {
```

```
        {
            // Get the matching cart and album instances
            var cartItem = storeDB.Carts.SingleOrDefault(
                c => c.CartId == ShoppingCartId
                && c.AlbumId == album.AlbumId);

            if (cartItem == null)
            {
                // Create a new cart item if no cart item exists
                cartItem = new Cart
                {
                    AlbumId = album.AlbumId,
                    CartId = ShoppingCartId,
                    Count = 1,
                    DateCreated = DateTime.Now
                };
                storeDB.Carts.Add(cartItem);
            }
            else
            {
                // If the item does exist in the cart,
                // then add one to the quantity
                cartItem.Count++;
            }
            // Save changes
            storeDB.SaveChanges();
        }
        public int RemoveFromCart(int id)
        {
            // Get the cart
            var cartItem = storeDB.Carts.Single(
                cart => cart.CartId == ShoppingCartId
                && cart.RecordId == id);

            int itemCount = 0;

            if (cartItem != null)
            {
                if (cartItem.Count > 1)
                {
                    cartItem.Count--;
                    itemCount = cartItem.Count;
                }
                else
                {
                    storeDB.Carts.Remove(cartItem);
                }
                // Save changes
                storeDB.SaveChanges();
            }
            return itemCount;
        }
        public void EmptyCart()
        {
            var cartItems = storeDB.Carts.Where(
                cart => cart.CartId == ShoppingCartId);

            foreach (var cartItem in cartItems)
            {
                storeDB.Carts.Remove(cartItem);
            }
            // Save changes
            storeDB.SaveChanges();
        }
        public List<Cart> GetCartItems()
        {
            return storeDB.Carts.Where(
                cart => cart.CartId == ShoppingCartId).ToList();
        }
```

```
        public int GetCount()
        {
            // Get the count of each item in the cart and sum them up
            int? count = (from cartItems in storeDB.Carts
                          where cartItems.CartId == ShoppingCartId
                          select (int?)cartItems.Count).Sum();
            // Return 0 if all entries are null
            return count ?? 0;
        }
        public decimal GetTotal()
        {
            // Multiply album price by count of that album to get
            // the current price for each of those albums in the cart
            // sum all album price totals to get the cart total
            decimal? total = (from cartItems in storeDB.Carts
                              where cartItems.CartId == ShoppingCartId
                              select (int?)cartItems.Count *
                              cartItems.Album.Price).Sum();

            return total ?? decimal.Zero;
        }
        public int CreateOrder(Order order)
        {
            decimal orderTotal = 0;

            var cartItems = GetCartItems();
            // Iterate over the items in the cart,
            // adding the order details for each
            foreach (var item in cartItems)
            {
                var orderDetail = new OrderDetail
                {
                    AlbumId = item.AlbumId,
                    OrderId = order.OrderId,
                    UnitPrice = item.Album.Price,
                    Quantity = item.Count
                };
                // Set the order total of the shopping cart
                orderTotal += (item.Count * item.Album.Price);

                storeDB.OrderDetails.Add(orderDetail);

            }
            // Set the order's total to the orderTotal count
            order.Total = orderTotal;

            // Save the order
            storeDB.SaveChanges();
            // Empty the shopping cart
            EmptyCart();
            // Return the OrderId as the confirmation number
            return order.OrderId;
        }
        // We're using HttpContextBase to allow access to cookies.
        public string GetCartId(HttpContextBase context)
        {
            if (context.Session[CartSessionKey] == null)
            {
                if (!string.IsNullOrWhiteSpace(context.User.Identity.Name))
                {
                    context.Session[CartSessionKey] =
                        context.User.Identity.Name;
                }
                else
                {
                    // Generate a new random GUID using System.Guid class
                    Guid tempCartId = Guid.NewGuid();
                    // Send tempCartId back to client as a cookie
                    context.Session[CartSessionKey] = tempCartId.ToString();
```

```
                }
            }
            return context.Session[CartSessionKey].ToString();
        }
        // When a user has logged in, migrate their shopping cart to
        // be associated with their username
        public void MigrateCart(string userName)
        {
            var shoppingCart = storeDB.Carts.Where(
                c => c.CartId == ShoppingCartId);

            foreach (Cart item in shoppingCart)
            {
                item.CartId = userName;
            }
            storeDB.SaveChanges();
        }
    }
}
```

ViewModels

Our Shopping Cart Controller will need to communicate some complex information to its views which doesn't map cleanly to our Model objects. We don't want to modify our Models to suit our views; Model classes should represent our domain, not the user interface. One solution would be to pass the information to our Views using the ViewBag class, as we did with the Store Manager dropdown information, but passing a lot of information via ViewBag gets hard to manage.

A solution to this is to use the *ViewModel* pattern. When using this pattern we create strongly-typed classes that are optimized for our specific view scenarios, and which expose properties for the dynamic values/content needed by our view templates. Our controller classes can then populate and pass these view-optimized classes to our view template to use. This enables type-safety, compile-time checking, and editor IntelliSense within view templates.

We'll create two View Models for use in our Shopping Cart controller: the ShoppingCartViewModel will hold the contents of the user's shopping cart, and the ShoppingCartRemoveViewModel will be used to display confirmation information when a user removes something from their cart.

Let's create a new ViewModels folder in the root of our project to keep things organized. Right-click the project, select Add / New Folder.

Name the folder ViewModels.

Next, add the ShoppingCartViewModel class in the ViewModels folder. It has two properties: a list of Cart items, and a decimal value to hold the total price for all items in the cart.

```
using System.Collections.Generic;
using MvcMusicStore.Models;

namespace MvcMusicStore.ViewModels
{
    public class ShoppingCartViewModel
    {
        public List<Cart> CartItems { get; set; }
        public decimal CartTotal { get; set; }
    }
}
```

Now add the ShoppingCartRemoveViewModel to the ViewModels folder, with the following four properties.

```
namespace MvcMusicStore.ViewModels
{
    public class ShoppingCartRemoveViewModel
    {
        public string Message { get; set; }
        public decimal CartTotal { get; set; }
        public int CartCount { get; set; }
        public int ItemCount { get; set; }
        public int DeleteId { get; set; }
    }
}
```

The Shopping Cart Controller

The Shopping Cart controller has three main purposes: adding items to a cart, removing items from the cart, and viewing items in the cart. It will make use of the three classes we just created: ShoppingCartViewModel, ShoppingCartRemoveViewModel, and ShoppingCart. As in the StoreController and StoreManagerController, we'll add a field to hold an instance of MusicStoreEntities.

Add a new Shopping Cart controller to the project using the Empty controller template.

Here's the complete ShoppingCart Controller. The Index and Add Controller actions should look very familiar. The Remove and CartSummary controller actions handle two special cases, which we'll discuss in the following section.

```
using System.Linq;
using System.Web.Mvc;
using MvcMusicStore.Models;
using MvcMusicStore.ViewModels;

namespace MvcMusicStore.Controllers
{
    public class ShoppingCartController : Controller
    {
        MusicStoreEntities storeDB = new MusicStoreEntities();
        //
        // GET: /ShoppingCart/
        public ActionResult Index()
        {
            var cart = ShoppingCart.GetCart(this.HttpContext);

            // Set up our ViewModel
            var viewModel = new ShoppingCartViewModel
            {
                CartItems = cart.GetCartItems(),
                CartTotal = cart.GetTotal()
            };
            // Return the view
            return View(viewModel);
        }
        //
        // GET: /Store/AddToCart/5
        public ActionResult AddToCart(int id)
        {
            // Retrieve the album from the database
            var addedAlbum = storeDB.Albums
                .Single(album => album.AlbumId == id);

            // Add it to the shopping cart
            var cart = ShoppingCart.GetCart(this.HttpContext);

            cart.AddToCart(addedAlbum);

            // Go back to the main store page for more shopping
            return RedirectToAction("Index");
        }
        //
        // AJAX: /ShoppingCart/RemoveFromCart/5
```

```
        // AJAX: /ShoppingCart/RemoveFromCart/5
        [HttpPost]
        public ActionResult RemoveFromCart(int id)
        {
            // Remove the item from the cart
            var cart = ShoppingCart.GetCart(this.HttpContext);

            // Get the name of the album to display confirmation
            string albumName = storeDB.Carts
                .Single(item => item.RecordId == id).Album.Title;

            // Remove from cart
            int itemCount = cart.RemoveFromCart(id);

            // Display the confirmation message
            var results = new ShoppingCartRemoveViewModel
            {
                Message = Server.HtmlEncode(albumName) +
                    " has been removed from your shopping cart.",
                CartTotal = cart.GetTotal(),
                CartCount = cart.GetCount(),
                ItemCount = itemCount,
                DeleteId = id
            };
            return Json(results);
        }
        //
        // GET: /ShoppingCart/CartSummary
        [ChildActionOnly]
        public ActionResult CartSummary()
        {
            var cart = ShoppingCart.GetCart(this.HttpContext);

            ViewData["CartCount"] = cart.GetCount();
            return PartialView("CartSummary");
        }
    }
}
```

Ajax Updates with jQuery

We'll next create a Shopping Cart Index page that is strongly typed to the ShoppingCartViewModel and uses the List View template using the same method as before.

However, instead of using an Html.ActionLink to remove items from the cart, we'll use jQuery to "wire up" the click event for all links in this view which have the HTML class RemoveLink. Rather than posting the form, this click event handler will just make an AJAX callback to our RemoveFromCart controller action. The RemoveFromCart returns a JSON serialized result, which our jQuery callback then parses and performs four quick updates to the page using jQuery:

- 1. Removes the deleted album from the list
- 2. Updates the cart count in the header
- 3. Displays an update message to the user
- 4. Updates the cart total price

Since the remove scenario is being handled by an Ajax callback within the Index view, we don't need an additional view for RemoveFromCart action. Here is the complete code for the /ShoppingCart/Index view:

```
@model MvcMusicStore.ViewModels.ShoppingCartViewModel
@{
    ViewBag.Title = "Shopping Cart";
}
<script src="/Scripts/jquery-1.4.4.min.js"
type="text/javascript"></script>
<script type="text/javascript">
    $(function () {
        // Document.ready -> link up remove event handler
        $(".RemoveLink").click(function () {
            // Get the id from the link
            var recordToDelete = $(this).attr("data-id");
            if (recordToDelete != '') {
                // Perform the ajax post
                $.post("/ShoppingCart/RemoveFromCart", {"id": recordToDelete },
                    function (data) {
                        // Successful requests get here
                        // Update the page elements
                        if (data.ItemCount == 0) {
                            $('#row-' + data.DeleteId).fadeOut('slow');
                        } else {
                            $('#item-count-' + data.DeleteId).text(data.ItemCount);
                        }
```

```
                        $('#cart-total').text(data.CartTotal);
                        $('#update-message').text(data.Message);
                        $('#cart-status').text('Cart (' + data.CartCount + ')');
                    });
            }
        });
    });
</script>
<h3>
    <em>Review</em> your cart:
 </h3>
<p class="button">
    @Html.ActionLink("Checkout
>>", "AddressAndPayment", "Checkout")
</p>
<div id="update-message">
</div>
<table>
    <tr>
        <th>
            Album Name
        </th>
        <th>
            Price (each)
        </th>
        <th>
            Quantity
        </th>
        <th></th>
    </tr>
    @foreach (var item in
Model.CartItems)
    {
        <tr id="row-@item.RecordId">
            <td>
                @Html.ActionLink(item.Album.Title,
"Details", "Store", new { id = item.AlbumId }, null)
            </td>
            <td>
                @item.Album.Price
            </td>
            <td id="item-count-@item.RecordId">
                @item.Count
            </td>
            <td>
                <a href="#" class="RemoveLink"
data-id="@item.RecordId">Remove
from cart</a>
            </td>
        </tr>
    }
    <tr>
        <td>
            Total
        </td>
        <td>
        </td>
        <td>
        </td>
        <td id="cart-total">
            @Model.CartTotal
        </td>
    </tr>
</table>
```

In order to test this out, we need to be able to add items to our shopping cart. We'll update our **Store Details** view to include an "Add to cart" button. While we're at it, we can include some of the Album additional information

which we've added since we last updated this view: Genre, Artist, Price, and Album Art. The updated Store Details view code appears as shown below.

```
@model MvcMusicStore.Models.Album
@{
    ViewBag.Title = "Album - " + Model.Title;
 }
<h2>@Model.Title</h2>
<p>
    <img alt="@Model.Title"
src="@Model.AlbumArtUrl" />
</p>
<div id="album-details">
    <p>
        <em>Genre:</em>
        @Model.Genre.Name
    </p>
    <p>
        <em>Artist:</em>
        @Model.Artist.Name
    </p>
    <p>
        <em>Price:</em>
        @String.Format("{0:F}",
Model.Price)
    </p>
    <p class="button">
        @Html.ActionLink("Add to
cart", "AddToCart",
        "ShoppingCart", new { id = Model.AlbumId }, "")
    </p>
</div>
```

Now we can click through the store and test adding and removing Albums to and from our shopping cart. Run the application and browse to the Store Index.

Next, click on a Genre to view a list of albums.

Clicking on an Album title now shows our updated Album Details view, including the "Add to cart" button.

Clicking the "Add to cart" button shows our Shopping Cart Index view with the shopping cart summary list.

After loading up your shopping cart, you can click on the Remove from cart link to see the Ajax update to your shopping cart.

We've built out a working shopping cart which allows unregistered users to add items to their cart. In the following section, we'll allow them to register and complete the checkout process.

Part 9: Registration and Checkout

2/20/2020 • 9 minutes to read • Edit Online

by Jon Galloway

The MVC Music Store is a tutorial application that introduces and explains step-by-step how to use ASP.NET MVC and Visual Studio for web development.

The MVC Music Store is a lightweight sample store implementation which sells music albums online, and implements basic site administration, user sign-in, and shopping cart functionality.

This tutorial series details all of the steps taken to build the ASP.NET MVC Music Store sample application. Part 9 covers Registration and Checkout.

In this section, we will be creating a CheckoutController which will collect the shopper's address and payment information. We will require users to register with our site prior to checking out, so this controller will require authorization.

Users will navigate to the checkout process from their shopping cart by clicking the "Checkout" button.

If the user is not logged in, they will be prompted to.

Upon successful login, the user is then shown the Address and Payment view.

Once they have filled the form and submitted the order, they will be shown the order confirmation screen.

Attempting to view either a non-existent order or an order that doesn't belong to you will show the Error view.

Migrating the Shopping Cart

While the shopping process is anonymous, when the user clicks on the Checkout button, they will be required to register and login. Users will expect that we will maintain their shopping cart information between visits, so we will need to associate the shopping cart information with a user when they complete registration or login.

This is actually very simple to do, as our ShoppingCart class already has a method which will associate all the items in the current cart with a username. We will just need to call this method when a user completes registration or login.

Open the **AccountController** class that we added when we were setting up Membership and Authorization. Add a using statement referencing MvcMusicStore.Models, then add the following MigrateShoppingCart method:

```
private void MigrateShoppingCart(string UserName)
{
    // Associate shopping cart items with logged-in user
    var cart = ShoppingCart.GetCart(this.HttpContext);

    cart.MigrateCart(UserName);
    Session[ShoppingCart.CartSessionKey] = UserName;
}
```

Next, modify the LogOn post action to call MigrateShoppingCart after the user has been validated, as shown below:

```
//
// POST: /Account/LogOn
[HttpPost]
 public ActionResult LogOn(LogOnModel model, string returnUrl)
 {
    if (ModelState.IsValid)
    {
        if (Membership.ValidateUser(model.UserName, model.Password))
        {
            MigrateShoppingCart(model.UserName);

            FormsAuthentication.SetAuthCookie(model.UserName,
                model.RememberMe);
            if (Url.IsLocalUrl(returnUrl) && returnUrl.Length > 1
                && returnUrl.StartsWith("/")
                && !returnUrl.StartsWith("//") &&
                !returnUrl.StartsWith("/\\"))
            {
                return Redirect(returnUrl);
            }
            else
            {
                return RedirectToAction("Index", "Home");
            }
        }
        else
        {
            ModelState.AddModelError("", "The user name or password provided is incorrect.");
        }
    }
    // If we got this far, something failed, redisplay form
    return View(model);
 }
```

Make the same change to the Register post action, immediately after the user account is successfully created:

```
//
// POST: /Account/Register
[HttpPost]
 public ActionResult Register(RegisterModel model)
 {
    if (ModelState.IsValid)
    {
        // Attempt to register the user
        MembershipCreateStatus createStatus;
        Membership.CreateUser(model.UserName, model.Password, model.Email,
               "question", "answer", true, null, out
               createStatus);

        if (createStatus == MembershipCreateStatus.Success)
        {
            MigrateShoppingCart(model.UserName);

            FormsAuthentication.SetAuthCookie(model.UserName, false /*
                  createPersistentCookie */);
            return RedirectToAction("Index", "Home");
        }
        else
        {
            ModelState.AddModelError("", ErrorCodeToString(createStatus));
        }
    }
    // If we got this far, something failed, redisplay form
    return View(model);
 }
```

That's it - now an anonymous shopping cart will be automatically transferred to a user account upon successful registration or login.

Creating the CheckoutController

Right-click on the Controllers folder and add a new Controller to the project named CheckoutController using the Empty controller template.

First, add the Authorize attribute above the Controller class declaration to require users to register before checkout:

```
namespace MvcMusicStore.Controllers
{
    [Authorize]
    public class CheckoutController : Controller
```

Note: This is similar to the change we previously made to the StoreManagerController, but in that case the Authorize attribute required that the user be in an Administrator role. In the Checkout Controller, we're requiring the user be logged in but aren't requiring that they be administrators.

For the sake of simplicity, we won't be dealing with payment information in this tutorial. Instead, we are allowing users to check out using a promotional code. We will store this promotional code using a constant named PromoCode.

As in the StoreController, we'll declare a field to hold an instance of the MusicStoreEntities class, named storeDB. In order to make use of the MusicStoreEntities class, we will need to add a using statement for the MvcMusicStore.Models namespace. The top of our Checkout controller appears below.

```
using System;
using System.Linq;
using System.Web.Mvc;
using MvcMusicStore.Models;

namespace MvcMusicStore.Controllers
{
    [Authorize]
    public class CheckoutController : Controller
    {
        MusicStoreEntities storeDB = new MusicStoreEntities();
        const string PromoCode = "FREE";
```

The CheckoutController will have the following controller actions:

AddressAndPayment (GET method) will display a form to allow the user to enter their information.

AddressAndPayment (POST method) will validate the input and process the order.

Complete will be shown after a user has successfully finished the checkout process. This view will include the user's order number, as confirmation.

First, let's rename the Index controller action (which was generated when we created the controller) to AddressAndPayment. This controller action just displays the checkout form, so it doesn't require any model information.

```
//
// GET: /Checkout/AddressAndPayment
public ActionResult AddressAndPayment()
{
    return View();
}
```

Our AddressAndPayment POST method will follow the same pattern we used in the StoreManagerController: it will try to accept the form submission and complete the order, and will re-display the form if it fails.

After validating the form input meets our validation requirements for an Order, we will check the PromoCode form value directly. Assuming everything is correct, we will save the updated information with the order, tell the ShoppingCart object to complete the order process, and redirect to the Complete action.

```
//
// POST: /Checkout/AddressAndPayment
[HttpPost]
public ActionResult AddressAndPayment(FormCollection values)
{
    var order = new Order();
    TryUpdateModel(order);

    try
    {
        if (string.Equals(values["PromoCode"], PromoCode,
            StringComparison.OrdinalIgnoreCase) == false)
        {
            return View(order);
        }
        else
        {
            order.Username = User.Identity.Name;
            order.OrderDate = DateTime.Now;

            //Save Order
            storeDB.Orders.Add(order);
            storeDB.SaveChanges();
            //Process the order
            var cart = ShoppingCart.GetCart(this.HttpContext);
            cart.CreateOrder(order);

            return RedirectToAction("Complete",
                new { id = order.OrderId });
        }
    }
    catch
    {
        //Invalid - redisplay with errors
        return View(order);
    }
}
```

Upon successful completion of the checkout process, users will be redirected to the Complete controller action. This action will perform a simple check to validate that the order does indeed belong to the logged-in user before showing the order number as a confirmation.

```
//
// GET: /Checkout/Complete
public ActionResult Complete(int id)
{
    // Validate customer owns this order
    bool isValid = storeDB.Orders.Any(
        o => o.OrderId == id &&
        o.Username == User.Identity.Name);

    if (isValid)
    {
        return View(id);
    }
    else
    {
        return View("Error");
    }
}
```

Note: The Error view was automatically created for us in the /Views/Shared folder when we began the project.

The complete CheckoutController code is as follows:

```
using System;
using System.Linq;
using System.Web.Mvc;
using MvcMusicStore.Models;

namespace MvcMusicStore.Controllers
{
    [Authorize]
    public class CheckoutController : Controller
    {
        MusicStoreEntities storeDB = new MusicStoreEntities();
        const string PromoCode = "FREE";
        //
        // GET: /Checkout/AddressAndPayment
        public ActionResult AddressAndPayment()
        {
            return View();
        }
        //
        // POST: /Checkout/AddressAndPayment
        [HttpPost]
        public ActionResult AddressAndPayment(FormCollection values)
        {
            var order = new Order();
            TryUpdateModel(order);

            try
            {
                if (string.Equals(values["PromoCode"], PromoCode,
                    StringComparison.OrdinalIgnoreCase) == false)
                {
                    return View(order);
                }
                else
                {
                    order.Username = User.Identity.Name;
                    order.OrderDate = DateTime.Now;

                    //Save Order
                    storeDB.Orders.Add(order);
                    storeDB.SaveChanges();
                    //Process the order
                    var cart = ShoppingCart.GetCart(this.HttpContext);
                    cart.CreateOrder(order);

                    return RedirectToAction("Complete",
                        new { id = order.OrderId });
                }
            }
            catch
            {
                //Invalid - redisplay with errors
                return View(order);
            }
        }
        //
        // GET: /Checkout/Complete
        public ActionResult Complete(int id)
        {
            // Validate customer owns this order
            bool isValid = storeDB.Orders.Any(
                o => o.OrderId == id &&
                o.Username == User.Identity.Name);

            if (isValid)
            {
                return View(id);
            }
```

```
            else
            {
                return View("Error");
            }
        }
    }
}
```

Adding the AddressAndPayment view

Now, let's create the AddressAndPayment view. Right-click on one of the AddressAndPayment controller actions and add a view named AddressAndPayment which is strongly typed as an Order and uses the Edit template, as shown below.

This view will make use of two of the techniques we looked at while building the StoreManagerEdit view:

- We will use Html.EditorForModel() to display form fields for the Order model
- We will leverage validation rules using an Order class with validation attributes

We'll start by updating the form code to use Html.EditorForModel(), followed by an additional textbox for the Promo Code. The complete code for the AddressAndPayment view is shown below.

```
@model MvcMusicStore.Models.Order
@{
    ViewBag.Title = "Address And Payment";
}
<script src="@Url.Content("~/Scripts/jquery.validate.min.js")"
type="text/javascript"></script>
<script src="@Url.Content("~/Scripts/jquery.validate.unobtrusive.min.js")"
type="text/javascript"></script>
@using (Html.BeginForm()) {

    <h2>Address And Payment</h2>
    <fieldset>
        <legend>Shipping Information</legend>
        @Html.EditorForModel()
    </fieldset>
    <fieldset>
        <legend>Payment</legend>
        <p>We're running a promotion: all music is free
            with the promo code: "FREE"</p>
        <div class="editor-label">
            @Html.Label("Promo Code")
        </div>
        <div class="editor-field">
            @Html.TextBox("PromoCode")
        </div>
    </fieldset>

    <input type="submit" value="Submit Order" />
}
```

Defining validation rules for the Order

Now that our view is set up, we will set up the validation rules for our Order model as we did previously for the Album model. Right-click on the Models folder and add a class named Order. In addition to the validation attributes we used previously for the Album, we will also be using a Regular Expression to validate the user's email address.

```
using System.Collections.Generic;
using System.ComponentModel;
using System.ComponentModel.DataAnnotations;
using System.Web.Mvc;

namespace MvcMusicStore.Models
{
    [Bind(Exclude = "OrderId")]
    public partial class Order
    {
        [ScaffoldColumn(false)]
        public int OrderId { get; set; }
        [ScaffoldColumn(false)]
        public System.DateTime OrderDate { get; set; }
        [ScaffoldColumn(false)]
        public string Username { get; set; }
        [Required(ErrorMessage = "First Name is required")]
        [DisplayName("First Name")]
        [StringLength(160)]
        public string FirstName { get; set; }
        [Required(ErrorMessage = "Last Name is required")]
        [DisplayName("Last Name")]
        [StringLength(160)]
        public string LastName { get; set; }
        [Required(ErrorMessage = "Address is required")]
        [StringLength(70)]
        public string Address { get; set; }
        [Required(ErrorMessage = "City is required")]
        [StringLength(40)]
        public string City { get; set; }
        [Required(ErrorMessage = "State is required")]
        [StringLength(40)]
        public string State { get; set; }
        [Required(ErrorMessage = "Postal Code is required")]
        [DisplayName("Postal Code")]
        [StringLength(10)]
        public string PostalCode { get; set; }
        [Required(ErrorMessage = "Country is required")]
        [StringLength(40)]
        public string Country { get; set; }
        [Required(ErrorMessage = "Phone is required")]
        [StringLength(24)]
        public string Phone { get; set; }
        [Required(ErrorMessage = "Email Address is required")]
        [DisplayName("Email Address")]

        [RegularExpression(@"[A-Za-z0-9._%+-]+@[A-Za-z0-9.-]+\.[A-Za-z]{2,4}",
            ErrorMessage = "Email is is not valid.")]
        [DataType(DataType.EmailAddress)]
        public string Email { get; set; }
        [ScaffoldColumn(false)]
        public decimal Total { get; set; }
        public List<OrderDetail> OrderDetails { get; set; }
    }
}
```

Attempting to submit the form with missing or invalid information will now show error message using client-side validation.

Okay, we've done most of the hard work for the checkout process; we just have a few odds and ends to finish. We need to add two simple views, and we need to take care of the handoff of the cart information during the login process.

Adding the Checkout Complete view

The Checkout Complete view is pretty simple, as it just needs to display the Order ID. Right-click on the Complete controller action and add a view named Complete which is strongly typed as an int.

Now we will update the view code to display the Order ID, as shown below.

```
@model int
@{
    ViewBag.Title = "Checkout Complete";
}
<h2>Checkout Complete</h2>
<p>Thanks for your order! Your order number is: @Model</p>
<p>How about shopping for some more music in our
    @Html.ActionLink("store",
"Index", "Home")
</p>
```

Updating The Error view

The default template includes an Error view in the Shared views folder so that it can be re-used elsewhere in the site. This Error view contains a very simple error and doesn't use our site Layout, so we'll update it.

Since this is a generic error page, the content is very simple. We'll include a message and a link to navigate to the previous page in history if the user wants to re-try their action.

```
@{
    ViewBag.Title = "Error";
}

<h2>Error</h2>

<p>We're sorry, we've hit an unexpected error.
    <a href="javascript:history.go(-1)">Click here</a>
    if you'd like to go back and try that again.</p>
```

Part 10: Final Updates to Navigation and Site Design, Conclusion

2/20/2020 • 6 minutes to read • Edit Online

by Jon Galloway

> The MVC Music Store is a tutorial application that introduces and explains step-by-step how to use ASP.NET MVC and Visual Studio for web development.
>
> The MVC Music Store is a lightweight sample store implementation which sells music albums online, and implements basic site administration, user sign-in, and shopping cart functionality.
>
> This tutorial series details all of the steps taken to build the ASP.NET MVC Music Store sample application. Part 10 covers Final Updates to Navigation and Site Design, Conclusion.

We've completed all the major functionality for our site, but we still have some features to add to the site navigation, the home page, and the Store Browse page.

Creating the Shopping Cart Summary Partial View

We want to expose the number of items in the user's shopping cart across the entire site.

We can easily implement this by creating a partial view which is added to our Site.master.

As shown previously, the ShoppingCart controller includes a CartSummary action method which returns a partial view:

```
//
// GET: /ShoppingCart/CartSummary
[ChildActionOnly]
 public ActionResult CartSummary()
{
    var cart = ShoppingCart.GetCart(this.HttpContext);

    ViewData["CartCount"] = cart.GetCount();
    return PartialView("CartSummary");
}
```

To create the CartSummary partial view, right-click on the Views/ShoppingCart folder and select Add View. Name the view CartSummary and check the "Create a partial view" checkbox as shown below.

The CartSummary partial view is really simple - it's just a link to the ShoppingCart Index view which shows the number of items in the cart. The complete code for CartSummary.cshtml is as follows:

```
@Html.ActionLink("Cart
(" + ViewData["CartCount"] + ")",
    "Index",
    "ShoppingCart",
    new { id = "cart-status" })
```

We can include a partial view in any page in the site, including the Site master, by using the Html.RenderAction method. RenderAction requires us to specify the Action Name ("CartSummary") and the Controller Name ("ShoppingCart") as below.

```
@Html.RenderAction("CartSummary",
"ShoppingCart")
```

Before adding this to the site Layout, we will also create the Genre Menu so we can make all of our Site.master updates at one time.

Creating the Genre Menu Partial View

We can make it a lot easier for our users to navigate through the store by adding a Genre Menu which lists all the Genres available in our store.

We will follow the same steps also create a GenreMenu partial view, and then we can add them both to the Site master. First, add the following GenreMenu controller action to the StoreController:

```
//
// GET: /Store/GenreMenu
[ChildActionOnly]
 public ActionResult GenreMenu()
{
    var genres = storeDB.Genres.ToList();
    return PartialView(genres);
 }
```

This action returns a list of Genres which will be displayed by the partial view, which we will create next.

Note: We have added the [ChildActionOnly] attribute to this controller action, which indicates that we only want this action to be used from a Partial View. This attribute will prevent the controller action from being executed by browsing to /Store/GenreMenu. This isn't required for partial views, but it is a good practice, since we want to make sure our controller actions are used as we intend. We are also returning PartialView rather than View, which lets the view engine know that it shouldn't use the Layout for this view, as it is being included in other views.

Right-click on the GenreMenu controller action and create a partial view named GenreMenu which is strongly typed using the Genre view data class as shown below.

Update the view code for the GenreMenu partial view to display the items using an unordered list as follows.

```
@model IEnumerable<MvcMusicStore.Models.Genre>
<ul id="categories">
    @foreach (var genre in Model)
    {
        <li>@Html.ActionLink(genre.Name,
                "Browse", "Store",
                new { Genre = genre.Name }, null)
        </li>
    }
</ul>
```

Updating Site Layout to display our Partial Views

We can add our partial views to the Site Layout (/Views/Shared/_Layout.cshtml) by calling Html.RenderAction(). We'll add them both in, as well as some additional markup to display them, as shown below:

```
<!DOCTYPE html>
<html>
<head>
    <title>@ViewBag.Title</title>
    <link href="@Url.Content("~/Content/Site.css")"
rel="stylesheet"
        type="text/css" />
    <script src="@Url.Content("~/Scripts/jquery-1.4.4.min.js")"
        type="text/javascript"></script>
</head>
<body>
    <div id="header">
        <h1><a href="/">ASP.NET MVC MUSIC
STORE</a></h1>
        <ul id="navlist">
            <li class="first">
                <a href="@Url.Content("~")" id="current">
                    Home</a></li>
            <li><a href="@Url.Content("~/Store/")">Store</a></li>
            <li>@{Html.RenderAction("CartSummary", "ShoppingCart");}</li>
            <li><a href="@Url.Content("~/StoreManager/")">
                    Admin</a></li>
        </ul>
    </div>
    @{Html.RenderAction("GenreMenu", "Store");}
    <div id="main">
        @RenderBody()
    </div>
    <div id="footer">
        built with <a href="http://asp.net/mvc">ASP.NET MVC 3</a>
    </div>
</body>
</html>
```

Now when we run the application, we will see the Genre in the left navigation area and the Cart Summary at the top.

Update to the Store Browse page

The Store Browse page is functional, but doesn't look very good. We can update the page to show the albums in a better layout by updating the view code (found in /Views/Store/Browse.cshtml) as follows:

```
@model MvcMusicStore.Models.Genre

@{
    ViewBag.Title = "Browse Albums";
}

<div class="genre">
    <h3><em>@Model.Name</em> Albums</h3>

    <ul id="album-list">
        @foreach (var album in Model.Albums)
        {
            <li>
                <a href="@Url.Action("Details",
                    new { id = album.AlbumId })">
                    <img alt="@album.Title"
                        src="@album.AlbumArtUrl" />
                    <span>@album.Title</span>
                </a>
            </li>
        }
    </ul>
</div>
```

Here we are making use of Url.Action rather than Html.ActionLink so that we can apply special formatting to the link to include the album artwork.

Note: We are displaying a generic album cover for these albums. This information is stored in the database and is editable via the Store Manager. You are welcome to add your own artwork.

Now when we browse to a Genre, we will see the albums shown in a grid with the album artwork.

Updating the Home Page to show Top Selling Albums

We want to feature our top selling albums on the home page to increase sales. We'll make some updates to our HomeController to handle that, and add in some additional graphics as well.

First, we'll add a navigation property to our Album class so that EntityFramework knows that they're associated. The last few lines of our **Album** class should now look like this:

```
public virtual Genre  Genre                 { get; set; }
public virtual Artist Artist                { get; set; }
public virtual List<OrderDetail>OrderDetails { get; set; }
    }
}
```

Note: This will require adding a using statement to bring in the System.Collections.Generic namespace.

First, we'll add a storeDB field and the MvcMusicStore.Models using statements, as in our other controllers. Next, we'll add the following method to the HomeController which queries our database to find top selling albums according to OrderDetails.

```
private List<Album> GetTopSellingAlbums(int count)
 {
    // Group the order details by album and return
    // the albums with the highest count
    return storeDB.Albums
        .OrderByDescending(a => a.OrderDetails.Count())
        .Take(count)
        .ToList();
}
```

This is a private method, since we don't want to make it available as a controller action. We are including it in the HomeController for simplicity, but you are encouraged to move your business logic into separate service classes as appropriate.

With that in place, we can update the Index controller action to query the top 5 selling albums and return them to the view.

```
public ActionResult Index()
{
    // Get most popular albums
    var albums = GetTopSellingAlbums(5);

    return View(albums);
 }
```

The complete code for the updated HomeController is as shown below.

```
using System.Collections.Generic;
using System.Linq;
using System.Web.Mvc;
using MvcMusicStore.Models;

namespace MvcMusicStore.Controllers
{
    public class HomeController : Controller
    {
        //
        // GET: /Home/
        MusicStoreEntities storeDB = new MusicStoreEntities();
        public ActionResult Index()
        {
            // Get most popular albums
            var albums = GetTopSellingAlbums(5);

            return View(albums);
        }
        private List<Album> GetTopSellingAlbums(int count)
        {
            // Group the order details by album and return
            // the albums with the highest count
            return storeDB.Albums
                .OrderByDescending(a => a.OrderDetails.Count())
                .Take(count)
                .ToList();
        }
    }
}
```

Finally, we'll need to update our Home Index view so that it can display a list of albums by updating the Model type and adding the album list to the bottom. We will take this opportunity to also add a heading and a promotion section to the page.

```
@model List<MvcMusicStore.Models.Album>
@{
    ViewBag.Title = "ASP.NET MVC Music Store";
}
<div id="promotion">
</div>
<h3><em>Fresh</em> off the grill</h3>
<ul id="album-list">
    @foreach (var album in Model)
    {
        <li><a href="@Url.Action("Details", "Store",
                new { id = album.AlbumId })">
            <img alt="@album.Title" src="@album.AlbumArtUrl" />
            <span>@album.Title</span>
</a>
        </li>
    }
</ul>
```

Now when we run the application, we'll see our updated home page with top selling albums and our promotional message.

Conclusion

We've seen that ASP.NET MVC makes it easy to create a sophisticated website with database access, membership, AJAX, etc. pretty quickly. Hopefully this tutorial has given you the tools you need to get started building your own ASP.NET MVC applications!

Using the HTML5 and jQuery UI Datepicker Popup Calendar with ASP.NET MVC - Part 1

2/20/2020 • 4 minutes to read • Edit Online

by Rick Anderson

> This tutorial will teach you the basics of how to work with editor templates, display templates, and the jQuery UI datepicker popup calendar in an ASP.NET MVC Web application.

This tutorial will teach you the basics of how to work with editor templates, display templates, and the jQuery UI datepicker popup calendar in an ASP.NET MVC Web application. For this tutorial, you can use Microsoft Visual Web Developer 2010 Express Service Pack 1 ("Visual Web Developer"), which is a free version of Microsoft Visual Studio, or you can use Visual Studio 2010 SP1 if you already have that.

Before you start, make sure you've installed the prerequisites listed below. You can install all of them by clicking the following link: Web Platform Installer. Alternatively, you can individually install the required software using the following links:

- Visual Studio Web Developer Express SP1 prerequisites
- ASP.NET MVC 3 Tools Update
- SQL Server Compact 4.0(runtime + tools support)

If you're using Visual Studio 2010 instead of Visual Web Developer, install the prerequisites by clicking the following link: Visual Studio 2010 prerequisites.

This tutorial assumes you have completed the Getting Started with MVC 3 tutorial or that you're familiar with ASP.NET MVC development. This tutorial starts with the completed project from the Getting Started with MVC 3 tutorial.

This tutorial shows code in C#. However, the starter project and completed project are also available in Visual Basic.

A Visual Studio project with C# and Visual Basic source code is available to accompany this topic: Download.

What You'll Build

You'll add templates (specifically, edit and display templates) to the simple movie-listing application that was created in the Getting Started with MVC 3 tutorial. You will also add a jQuery UI datepicker popup calendar to simplify the process of entering dates. The following screenshot shows the modified application with the jQuery UI datepicker popup calendar displayed.

Skills You'll Learn

Here's what you'll learn:

- How to use attributes from the DataAnnotations namespace to control the format of data when it's displayed and when it's in edit mode.
- How to create templates (edit and display templates) to control the formatting of data.
- How to add the jQuery UI datepicker as a way to enter date fields.

Getting Started

If you don't already have the movie-listing application from the starter project, download it:

- Download.
- In Windows Explorer, right-click the *MvcMovie.zip* file and select **Properties**.
- In the **MvcMovie.zip Properties** dialog box, select **Unblock**. (Unblocking prevents a security warning that occurs when you try to use a *.zip* file that you've downloaded from the web.)

Right-click the *MvcMovie.zip* file and select **Extract All** to unzip the file. In Visual Web Developer or Visual Studio 2010, open the *MvcMovieCS_TU.sln* file.

In **Solution Explorer**, double-click the *Views\Shared_Layout.cshtml* to open it. Change the `H1` header from **MVC Movie App** to **Movie jQuery**. Press CTRL+F5 to run the application and click the **Home** tab, which takes you to the `Index` method of the movie controller. To try out the application, select the **Edit** link and the **Details** link for one of the movies. Notice that in the Index, Edit, and Details views, the release date and price are nicely formatted:

The formatting for the date and the price is the result of using the DisplayFormat attribute on properties of the `Movie` class.

Open the *Movie.cs* file and comment out the `DisplayFormat` attribute on the `ReleaseDate` and `Price` properties. The resulting `Movie` class looks like this:

```
public class Movie {
    public int ID { get; set; }

    [Required(ErrorMessage = "Title is required")]
    public string Title { get; set; }

    //  [DisplayFormat(DataFormatString = "{0:d}")]
    public DateTime ReleaseDate { get; set; }

    [Required(ErrorMessage = "Genre must be specified")]
    public string Genre { get; set; }

    [Range(1, 100, ErrorMessage = "Price must be between $1 and $100")]
    //[DisplayFormat(DataFormatString = "{0:c}")]
    public decimal Price { get; set; }

    [StringLength(5)]
    public string Rating { get; set; }
}
```

Press CTRL+F5 again to run the application and select the **Home** tab to view the movie list. This time the release date shows the date and time, and the price field no longer shows the currency symbol. Your change in the `Movie`

class has undone the nice formatting that you saw earlier, but you'll fix that in a moment.

Using the DataAnnotations DataType Attribute to Specify the Data Type

Replace the commented-out `DisplayFormat` attribute for the `ReleaseDate` property with the DataType attribute, using the `Date` enumeration. Replace the `DisplayFormat` attribute for the `Price` property with the DataType attribute again, this time using the `Currency` enumeration. This is what the completed code looks like:

```
public class Movie {
    public int ID { get; set; }

    [Required(ErrorMessage = "Title is required")]
    public string Title { get; set; }

    [DataType(DataType.Date)]
    public DateTime ReleaseDate { get; set; }

    [Required(ErrorMessage = "Genre must be specified")]
    public string Genre { get; set; }

    [Range(1, 100, ErrorMessage = "Price must be between $1 and $100")]
    [DataType(DataType.Currency)]
    public decimal Price { get; set; }

    [StringLength(5)]
    public string Rating { get; set; }
}
```

Run the application. Now the release date and the price properties are formatted correctly (that is, using

appropriate date and currency formats). The DataType attribute provides type metadata for the built-in ASP.NET MVC templates so that the fields render in the correct format. Using the `DataType` attribute is preferable to using the `DisplayFormat` attribute that was originally in the code, because the `DataType` attribute makes the model cleaner and more flexible for purposes like internationalization.

In the next section you'll see how to make custom templates to display date fields.

Using the HTML5 and jQuery UI Datepicker Popup Calendar with ASP.NET MVC - Part 2

2/20/2020 • 6 minutes to read • Edit Online

by Rick Anderson

> This tutorial will teach you the basics of how to work with editor templates, display templates, and the jQuery UI datepicker popup calendar in an ASP.NET MVC Web application.

Adding an Automatic DateTime Template

In the first part of this tutorial, you saw how you can add attributes to the model to explicitly specify formatting, and how you can explicitly specify the template that's used to render the model. For example, the DisplayFormat attribute in the following code explicitly specifies the formatting for the `ReleaseDate` property.

```
[DisplayFormat(DataFormatString = "{0:d}")]
public DateTime  ReleaseDate { get; set; }
```

In the following example, the DataType attribute, using the `Date` enumeration, specifies that the date template should be used to render the model. If there's no date template in your project, the built-in date template is used.

```
[DataType(DataType.Date)]
public DateTime  ReleaseDate { get; set; }
```

However, ASP.MVC can perform type matching using convention-over-configuration, by looking for a template that matches the name of a type. This lets you create a template that automatically formats data without using any attributes or code at all. For this part of the tutorial, you'll create a template that's automatically applied to model properties of type DateTime. You won't need to use an attribute or other configuration to specify that the template should be used to render all model properties of type DateTime.

You'll also learn a way to customize the display of individual properties or even individual fields.

To begin, let's remove existing formatting information and display full dates in the application.

Open the *Movie.cs* file and comment out the `DataType` attribute on the `ReleaseDate` property:

```
// [DataType(DataType.Date)]
public DateTime ReleaseDate { get; set; }
```

Press CTRL+F5 to run the application.

Notice that the `ReleaseDate` property now displays both the date and time, because that's the default when no formatting information is provided.

Adding CSS Styles for Testing New Templates

Before you create a template for formatting dates, you'll add a few CSS style rules that you can apply to the new templates. These will help you verify that the rendered page is using the new template.

Open the *Content\Site.cs*s file and add the following CSS rules to the bottom of the file:

```
/* Styles to test new editor and display templates.
-------------------------------------------------------------*/
.loud-1 {
    font-weight: bold;
    color: Red;
}
.loud-2 {
    font-size:  2.0em;
    color:Green;
}
.loud-3 {
    font-style: italic;
    color: yellow;
    background-color: blue;
}
```

Adding DateTime Display Templates

Now you can create the new template. In the *Views\Movies* folder, create a *DisplayTemplates* folder.

In the *Views\Shared* folder, create a *DisplayTemplates* folder and an *EditorTemplates* folder.

The display templates in the *Views\Shared\DisplayTemplates* folder will be used by all controllers. The display templates in the *Views\Movie\DisplayTemplates* folder will be used only by the `Movie` controller. (If a template with the same name appears in both folders, the template in the *Views\Movie\DisplayTemplates* folder — that is, the more specific template — takes precedence for views returned by the `Movie` controller.)

In **Solution Explorer**, expand the *Views* folder, expand the *Shared* folder, and then right-click the *Views\Shared\DisplayTemplates* folder.

Click **Add** and then click **View**. The **Add View** dialog box is displayed.

In the **View name** box, type `DateTime`. (You must use this name in order to match the name of the type.)

Select the **Create as a partial view** check box. Make sure that the **Use a layout or master page** and **Create a strongly-typed view** check boxes are not selected.

Click **Add**. A *DateTime.cshtml* template is created in the *Views\Shared\DisplayTemplates*.

The following image shows the *Views* folder in **Solution Explorer** after the `DateTime` display and editor templates are created.

Open the *Views\Shared\DisplayTemplates\DateTime.cshtml* file and add the following markup, which uses the String.Format method to format the property as a date without the time. (The `{0:d}` format specifies short date format.)

```
@String.Format("{0:d}", Model.Date)
```

Repeat this step to create a `DateTime` template in the *Views\Movie\DisplayTemplates* folder. Use the following code in the *Views\Movie\DisplayTemplates\DateTime.cshtml* file.

```
<span class="loud-1">
@String.Format("{0:d}", Model.Date)
</span>
```

The `loud-1` CSS class causes the date to be display in bold red text. You added the `loud-1` CSS class just as a temporary measure so you can easily see when this particular template is being used.

What you've done is created and customized templates that ASP.NET will use to display dates. The more general template (in the *Views\Shared\DisplayTemplates* folder) displays a simple short date. The template that's specifically for the `Movie` controller (in the *Views\Movies\DisplayTemplates* folder) displays a short date that's also formatted as bold red text.

Press CTRL+F5 to run the application. The browser renders the Index view for the application.

The `ReleaseDate` property now displays the date in a bold red font without the time.This helps you confirm that the `DateTime` templated helper in the *Views\Movies\DisplayTemplates* folder is selected over the `DateTime` templated helper in the shared folder (*Views\Shared\DisplayTemplates*).

Now rename the *Views\Movies\DisplayTemplates\DateTime.cshtml* file to *Views\Movies\DisplayTemplates\LoudDateTime.cshtml*.

Press CTRL+F5 to run the application.

This time the `ReleaseDate` property displays a date without the time and without the bold red font. This illustrates that a template that has the name of the data type (in this case `DateTime`) is automatically used to display all model properties of that type. After you renamed the *DateTime.cshtml* file to *LoudDateTime.cshtml*, ASP.NET no longer found a template in the *Views\Movies\DisplayTemplates* folder, so it used the *DateTime.cshtml* template from the *Views\Movies\Shared* folder.

(The template matching is case insensitive, so you could have created the template file name with any casing. For example, *DATETIME.cshtml, datetime.cshtml*, and *DaTeTiMe.cshtml* would all match the `DateTime` type.)

To review: at this point, the `ReleaseDate` field is being displayed using the *Views\Movies\DisplayTemplates\DateTime.cshtml* template, which displays the data using a short date format, but otherwise adds no special format.

Using UIHint to Specify a Display Template

If your web application has many `DateTime` fields and by default you want to display all or most of them in date-only format, the *DateTime.cshtml* template is a good approach. But what if you have a few dates where you want to display the full date and time? No problem. You can create an additional template and use the UIHint attribute to specify formatting for the full date and time. You can then selectively apply that template. You can use the UIHint attribute at the model level or you can specify the template inside a view. In this section, you'll see how to use the `UIHint` attribute to selectively change the formatting for some instances of date-time fields.

Open the *Views\Movies\DisplayTemplates\LoudDateTime.cshtml* file and replace the existing code with the following:

```
<span class="loud-2">
@Model.ToString()
</span>
```

This causes the full date and time to be displayed and adds the CSS class that makes the text green and large.

Open the *Movie.cs* file and add the UIHint attribute to the `ReleaseDate` property, as shown in the following example:

```
[UIHint("LoudDateTime")]
public DateTime ReleaseDate { get; set; }
```

This tells ASP.NET MVC that when it displays the `ReleaseDate` property (specifically, and not just any `DateTime` object), it should use the *LoudDateTime.cshtml* template.

Press CTRL+F5 to run the application.

Notice that the `ReleaseDate` property now displays the date and time in a large green font.

Return to the `UIHint` attribute in the *Movie.cs* file and comment it out so the *LoudDateTime.cshtml* template won't be used. Run the application again. The release date is not displayed large and green. This verifies that the *Views\Shared\DisplayTemplates\DateTime.cshtml* template is used in the Index and Details views.

As mentioned earlier, you can also apply a template in a view, which lets you apply the template to an individual instance of some data. Open the *Views\Movies\Details.cshtml* view. Add `"LoudDateTime"` as the second parameter of the Html.DisplayFor call for the `ReleaseDate` field. The completed code looks like this:

```
<div class="display-label">ReleaseDate</div>
<div class="display-field">
    @Html.DisplayFor(model => model.ReleaseDate,"LoudDateTime")
</div>
```

This specifies that the `LoudDateTime` template should be used to display the model property, regardless of what attributes are applied to the model.

Press CTRL+F5 to run the application.

Verify that the movie index page is using the *Views\Shared\DisplayTemplates\DateTime.cshtml* template (red bold) and the *Movie\Details* page is using the *Views\Movies\DisplayTemplates\LoudDateTime.cshtml* template (large and green).

In the next section, you'll create a template for a complex type.

Using the HTML5 and jQuery UI Datepicker Popup Calendar with ASP.NET MVC - Part 4

2/20/2020 • 9 minutes to read • Edit Online

by Rick Anderson

> This tutorial will teach you the basics of how to work with editor templates, display templates, and the jQuery UI datepicker popup calendar in an ASP.NET MVC Web application.

Adding a Template for Editing Dates

In this section you'll create a template for editing dates that will be applied when ASP.NET MVC displays UI for editing model properties that are marked with the **Date** enumeration of the DataType attribute. The template will render only the date; time will not be displayed. In the template you'll use the jQuery UI Datepicker popup calendar to provide a way to edit dates.

To begin, open the *Movie.cs* file and add the DataType attribute with the **Date** enumeration to the `ReleaseDate` property, as shown in the following code:

```
[DataType(DataType.Date)]
public DateTime ReleaseDate { get; set; }
```

This code causes the `ReleaseDate` field to be displayed without the time in both display templates and edit templates. If your application contains a *date.cshtml* template in the *Views\Shared\EditorTemplates* folder or in the *Views\Movies\EditorTemplates* folder, that template will be used to render any `DateTime` property while editing. Otherwise the built-in ASP.NET templating system will display the property as a date.

Press CTRL+F5 to run the application. Select an edit link to verify that the input field for the release date is showing only the date.

In **Solution Explorer**, expand the *Views* folder, expand the *Shared* folder, and then right-click the *Views\Shared\EditorTemplates* folder.

Click **Add**, and then click **View**. The **Add View** dialog box is displayed.

In the **View name** box, type "Date".

Select the **Create as a partial view** check box. Make sure that the **Use a layout or master page** and **Create a strongly-typed view** check boxes are not selected.

Click **Add**. The *Views\Shared\EditorTemplates\Date.cshtml* template is created.

Add the following code to the *Views\Shared\EditorTemplates\Date.cshtml* template.

```
@model DateTime
Using Date Template
@Html.TextBox("", String.Format("{0:d}", Model.ToShortDateString()),
  new { @class = "datefield", type = "date"  })
```

The first line declares the model to be a `DateTime` type. Although you don't need to declare the model type in edit and display templates, it's a best practice so that you get compile-time checking of the model being passed to the view. (Another benefit is that you then get IntelliSense for the model in the view in Visual Studio.) If the model type is not declared, ASP.NET MVC considers it a dynamic type and there's no compile-time type checking. If you declare

the model to be a `DateTime` type, it becomes strongly typed.

The second line is just literal HTML markup that displays "Using Date Template" before a date field. You'll use this line temporarily to verify that this date template is being used.

The next line is an Html.TextBox helper that renders an `input` field that's a text box. The third parameter for the helper uses an anonymous type to set the class for the text box to `datefield` and the type to `date`. (Because `class` is a reserved in C#, you need to use the `@` character to escape the `class` attribute in the C# parser.)

The `date` type is an HTML5 input type that enables HTML5-aware browsers to render a HTML5 calendar control. Later on you'll add some JavaScript to hook up the jQuery datepicker to the `Html.TextBox` element using the `datefield` class.

Press CTRL+F5 to run the application. You can verify that the `ReleaseDate` property in the edit view is using the edit template because the template displays "Using Date Template" just before the `ReleaseDate` text input box, as shown in this image:

In your browser, view the source of the page. (For example, right-click the page and select **View source**.) The following example shows some of the markup for the page, illustrating the `class` and `type` attributes in the rendered HTML.

```
<input class="datefield" data-val="true" data-val-required="Date is required"
      id="ReleaseDate" name="ReleaseDate" type="date" value="1/11/1989" />
```

Return to the *Views\Shared\EditorTemplates\Date.cshtml* template and remove the "Using Date Template" markup. Now the completed template looks like this:

```
@model DateTime
@Html.TextBox("", String.Format("{0:d}", Model.ToShortDateString()),
  new { @class = "datefield", type = "date" })
```

Adding a jQuery UI Datepicker Popup Calendar using NuGet

In this section you'll add the jQuery UI datepicker popup calendar to the date-edit template. The jQuery UI library provides support for animation, advanced effects, and customizable widgets. It's built on top of the jQuery JavaScript library. The datepicker popup calendar makes it easy and natural to enter dates using a calendar instead of entering a string. The popup calendar also limits users to legal dates — ordinary text entry for a date would let you enter something like `2/33/1999` (February 33rd, 1999), but the jQuery UI datepicker popup calendar won't allow that.

First, you have to install the jQuery UI libraries. To do that, you'll use NuGet, which is a package manager that's included in SP1 versions of Visual Studio 2010 and Visual Web Developer.

In Visual Web Developer, from the **Tools** menu, select **NuGet Package Manager** and then select **Manage NuGet Packages**.

Note: If the **Tools** menu doesn't display the **NuGet Package Manager** command, you need to install NuGet by following the instructions on the Installing NuGet page of the NuGet website.

If you're using Visual Studio instead of Visual Web Developer, from the **Tools** menu, select **NuGet Package Manager** and then select **Add Library Package Reference**.

In the **MVCMovie - Manage NuGet Packages** dialog box, click the **Online** tab on the left and then enter "jQuery.UI" in the search box. Select j **Query UI Widgets:Datepicker**, then select the **Install** button.

NuGet adds these debug versions and minified versions of jQuery UI Core and the jQuery UI date picker to your project:

- *jquery.ui.core.js*
- *jquery.ui.core.min.js*
- *jquery.ui.datepicker.js*
- *jquery.ui.datepicker.min.js*

Note: The debug versions (the files without the *.min.js* extension) are useful for debugging, but in a production site, you'd include only the minified versions.

To actually use the jQuery date picker, you need to create a jQuery script that will hook up the calendar widget to the edit template. In **Solution Explorer**, right-click the *Scripts* folder and select **Add**, then **New Item**, and then **JScript File**. Name the file *DatePickerReady.js*.

Add the following code to the *DatePickerReady.js* file:

```
$(function () {
    $(".datefield").datepicker();
});
```

If you're not familiar with jQuery, here's a brief explanation of what this does: the first line is the "jQuery ready" function, which is called when all the DOM elements in a page have loaded. The second line selects all DOM elements that have the class name `datefield`, then invokes the `datepicker` function for each of them. (Remember that you added the `datefield` class to the *Views\Shared\EditorTemplates\Date.cshtml* template earlier in the tutorial.)

Next, open the *Views\Shared_Layout.cshtml* file. You need to add references to the following files, which are all required so that you can use the date picker:

- *Content/themes/base/jquery.ui.core.css*
- *Content/themes/base/jquery.ui.datepicker.css*
- *Content/themes/base/jquery.ui.theme.css*
- *jquery.ui.core.min.js*
- *jquery.ui.datepicker.min.js*
- *DatePickerReady.js*

The following example shows the actual code that you should add at the bottom of the `head` element in the *Views\Shared_Layout.cshtml* file.

```
<link href="@Url.Content("~/Content/themes/base/jquery.ui.core.css")"
        rel="stylesheet" type="text/css" />
    <link href="@Url.Content("~/Content/themes/base/jquery.ui.datepicker.css")"
        rel="stylesheet"  type="text/css" />
    <link href="@Url.Content("~/Content/themes/base/jquery.ui.theme.css")"
        rel="stylesheet" type="text/css" />

    <script src="@Url.Content("~/Scripts/jquery.ui.core.min.js")"
        type="text/javascript"></script>
    <script src="@Url.Content("~/Scripts/jquery.ui.datepicker.min.js")"
        type="text/javascript"></script>
    <script src="@Url.Content("~/Scripts/DatePickerReady.js")"
        type="text/javascript"></script>
```

The complete `head` section is shown here:

```
<head>
    <meta charset="utf-8" />
    <title>@ViewBag.Title</title>
    <link href="@Url.Content("~/Content/Site.css")"
        rel="stylesheet" type="text/css" />
    <script src="@Url.Content("~/Scripts/jquery-1.5.1.min.js")"
        type="text/javascript"></script>
    <script src="@Url.Content("~/Scripts/modernizr-1.7.min.js")"
        type="text/javascript"></script>

    <link href="@Url.Content("~/Content/themes/base/jquery.ui.core.css")"
        rel="stylesheet" type="text/css" />
    <link href="@Url.Content("~/Content/themes/base/jquery.ui.datepicker.css")"
        rel="stylesheet"  type="text/css" />
    <link href="@Url.Content("~/Content/themes/base/jquery.ui.theme.css")"
        rel="stylesheet" type="text/css" />

    <script src="@Url.Content("~/Scripts/jquery.ui.core.min.js")"
        type="text/javascript"></script>
    <script src="@Url.Content("~/Scripts/jquery.ui.datepicker.min.js")"
        type="text/javascript"></script>
    <script src="@Url.Content("~/Scripts/DatePickerReady.js")"
        type="text/javascript"></script>
</head>
```

The URL content helper method converts the resource path to an absolute path. You must use `@URL.Content` to correctly reference these resources when the application is running on IIS.

Press CTRL+F5 to run the application. Select an edit link, then put the insertion point into the **ReleaseDate** field. The jQuery UI popup calendar is displayed.

Like most jQuery controls, the datepicker lets you customize it extensively. For information, see Visual Customization: Designing a jQuery UI theme on the jQuery UI site.

Supporting the HTML5 Date Input Control

As more browsers support HTML5, you'll want to use the native HTML5 input, such as the `date` input element, and not use the jQuery UI calendar. You can add logic to your application to automatically use HTML5 controls if the browser supports them. To do this, replace the contents of the *DatePickerReady.js* file with the following:

```
if (!Modernizr.inputtypes.date) {
    $(function () {
        $(".datefield").datepicker();
    });
}
```

The first line of this script uses Modernizr to verify that HTML5 date input is supported. If it's not supported, the jQuery UI date picker is hooked up instead. (Modernizr is an open-source JavaScript library that detects the availability of native implementations of HTML5 and CSS3. Modernizr is included in any new ASP.NET MVC projects that you create.)

After you've made this change, you can test it by using a browser that supports HTML5, such as Opera 11. Run the application using an HTML5-compatible browser and edit a movie entry. The HTML5 date control is used instead of the jQuery UI popup calendar:

Because new versions of browsers are implementing HTML5 incrementally, a good approach for now is to add code to your website that accommodates a wide variety of HTML5 support. For example, a more robust *DatePickerReady.js* script is shown below that lets your site support browsers that only partially support the HTML5 date control.

```
if (!Modernizr.inputtypes.date) {
    $(function () {
        $("input[type='date']")
                    .datepicker()
                    .get(0)
                    .setAttribute("type", "text");
    })
}
```

This script selects HTML5 `input` elements of type `date` that don't fully support the HTML5 date control. For those elements, it hooks up the jQuery UI popup calendar and then changes the `type` attribute from `date` to `text`. By changing the `type` attribute from `date` to `text`, partial HTML5 date support is eliminated. An even more robust *DatePickerReady.js* script can be found at JSFIDDLE.

Adding Nullable Dates to the Templates

If you use one of the existing date templates and pass a null date, you'll get a run-time error. To make the date templates more robust, you'll change them to handle null values. To support nullable dates, change the code in the *Views\Shared\DisplayTemplates\DateTime.cshtml* to the following:

```
@model Nullable<DateTime>
@(Model != null ? string.Format("{0:d}", Model) : string.Empty)
```

The code returns an empty string when the model is **null**.

Change the code in the *Views\Shared\EditorTemplates\Date.cshtml* file to the following:

```
@model Nullable<DateTime>

 @{
    DateTime dt = DateTime.Now;
    if (Model != null)
    {
       dt  = (System.DateTime) Model;

    }
    @Html.TextBox("", String.Format("{0:d}", dt.ToShortDateString()), new { @class = "datefield", type =
"date"  })
}
```

When this code runs, if the model is not null, the model's `DateTime` value is used. If the model is null, the current date is used instead.

Wrapup

This tutorial has covered the basics of ASP.NET templated helpers and shows you how to use the jQuery UI datepicker popup calendar in an ASP.NET MVC application. For more information, try these resources:

- For information on localization, see Rajeesh's blog JQueryUI Datepicker in ASP.NET MVC.
- For information about jQuery UI, see jQuery UI.
- For information about how to localize the datepicker control, see UI/Datepicker/Localization.
- For more information about the ASP.NET MVC templates, see Brad Wilson's blog series on ASP.NET MVC 2 Templates. Although the series was written for ASP.NET MVC 2, the material still applies for the current version of ASP.NET MVC.

Using the DropDownList Helper with ASP.NET MVC

2/20/2020 • 12 minutes to read • Edit Online

by Rick Anderson

This tutorial will teach you the basics of working with the DropDownList helper and the ListBox helper in an ASP.NET MVC Web application. You can use Microsoft Visual Web Developer 2010 Express Service Pack 1, which is a free version of Microsoft Visual Studio to follow the tutorial. Before you start, make sure you've installed the prerequisites listed below. You can install all of them by clicking the following link: Web Platform Installer. Alternatively, you can individually install the prerequisites using the following links:

- Visual Studio Web Developer Express SP1 prerequisites
- ASP.NET MVC 3 Tools Update
- SQL Server Compact 4.0(runtime + tools support)

If you're using Visual Studio 2010 instead of Visual Web Developer 2010, install the prerequisites by clicking the following link: Visual Studio 2010 prerequisites. This tutorial assumes you have completed the Intro to ASP.NET MVC tutorial or theASP.NET MVC Music Store tutorial or you are familiar with ASP.NET MVC development. This tutorial starts with a modified project from the ASP.NET MVC Music Store tutorial. You can download the starter project with the following link Download the C# version.

A Visual Web Developer project with the completed tutorial C# source code is available to accompany this topic. Download.

What You'll Build

You'll create action methods and views that use the DropDownList helper to select a category. You will also use `jQuery` to add an insert category dialog that can be used when a new category (such as genre or artist) is needed. Below is a screenshot of the Create view showing links to add a new genre and add a new artist.

Skills You'll Learn

Here's what you'll learn:

- How to use the DropDownList helper to select category data.
- How to add a **jQuery** dialog to add new categories.

Getting Started

Start by downloading the starter project with the following link, Download. In Windows Explorer, right click on the *DDL_Starter.zip* file and select properties. In the **DDL_Starter.zip Properties** dialog box, select Unblock.

Right click the DDL_Starter.zip file and select **Extract All** to unzip the file. Open the *StartMusicStore.sln* file with Visual Web Developer 2010 Express ("Visual Web Developer" or "VWD" for short) or Visual Studio 2010.

Press CTRL+F5 to run the application and click the **Test** link.

Select the **Select Movie Category (Simple)** link. A Movie Type Select list is displayed, with Comedy the

selected value.

Right click in the browser and select view source. The HTML for the page is displayed. The code below shows the HTML for the select element.

```
<form action="/Home/CategoryChosen" method="get">

<fieldset>Movie Type <select id="MovieType" name="MovieType">

<option value=""></option>

<option value="0">Action</option>

<option value="1">Drama</option>

<option selected="selected" value="2">Comedy</option>

<option value="3">Science Fiction</option>

</select>

<p><input type="submit" value="Submit" /> </p>

</fieldset>

</form>
```

You can see that each item in the select list has a value (0 for Action, 1 for Drama, 2 for Comedy and 3 for Science Fiction) and a display name (Action, Drama, Comedy and Science Fiction). The code above is standard HTML for a select list.

Change the select list to Drama and hit the **Submit** button. The URL in the browser is `http://localhost:2468/Home/CategoryChosen?MovieType=1` and the page displays **You Selected: 1**.

Open the *Controllers\HomeController.cs* file and examine the `SelectCategory` method.

```
public ActionResult SelectCategory() {

     List<SelectListItem> items = new List<SelectListItem>();

     items.Add(new SelectListItem { Text = "Action", Value = "0"});

     items.Add(new SelectListItem { Text = "Drama", Value = "1" });

     items.Add(new SelectListItem { Text = "Comedy", Value = "2", Selected = true });

     items.Add(new SelectListItem { Text = "Science Fiction", Value = "3" });

     ViewBag.MovieType = items;

     return View();

 }
```

The DropDownList helper used to create an HTML select list requires a **IEnumerable<SelectListItem >**, either explicitly or implicitly. That is, you can pass the **IEnumerable<SelectListItem >** explicitly to the DropDownList helper or you can add the **IEnumerable<SelectListItem >** to the ViewBag using the same name for the **SelectListItem** as the model property. Passing in the **SelectListItem** implicitly and explicitly is covered in the next part of the tutorial. The code above shows the simplest possible way to create an **IEnumerable<SelectListItem >** and populate it with text and values. Note the `Comedy` SelectListItem has the Selected property set to **true;** this will cause the rendered select list to show **Comedy** as the selected item in the list.

The **IEnumerable<SelectListItem >** created above is added to the ViewBag with the name MovieType. This is how we pass the **IEnumerable<SelectListItem >** implicitly to the DropDownList helper shown below.

Open the *Views\Home\SelectCategory.cshtml* file and examine the markup.

```
@{

    ViewBag.Title = "Category Select";

    Layout = "~/Views/Shared/_Simple_Layout.cshtml";

}

@using (Html.BeginForm("CategoryChosen", "Home", FormMethod.Get)) {

    <fieldset>

            Movie Type

            @Html.DropDownList("MovieType")

        <p>

            <input type="submit" value="Submit" />

        </p>

    </fieldset>

}
```

On the third line, we set the layout to Views/Shared/_Simple_Layout.cshtml, which is a simplified version of the standard layout file. We do this to keep the display and rendered HTML simple.

In this sample we are not changing the state of the application, so we will submit the data using an **HTTP GET**, not **HTTP POST**. See the W3C section Quick Checklist for Choosing HTTP GET or POST. Because we are not changing the application and posting the form, we use the Html.BeginForm overload that allows us to specify the action method, controller and form method (**HTTP POST** or **HTTP GET**). Typically views contain the Html.BeginForm overload that takes no parameters. The no parameter version defaults to posting the form data to the POST version of the same action method and controller.

The following line

```
@Html.DropDownList("MovieType")
```

passes a string argument to the **DropDownList** helper. This string, "MovieType" in our example, does two things:

- It provides the key for the **DropDownList** helper to find a **IEnumerable<SelectListItem >** in the **ViewBag**.
- It is data-bound to the MovieType form element. If the submit method is **HTTP GET**, `MovieType` will be a query string. If the submit method is **HTTP POST**, `MovieType` will be added in the message body. The following image shows the query string with the value of 1.

The following code shows the `CategoryChosen` method the form was submitted to.

```
public ViewResult CategoryChosen(string MovieType) {

    ViewBag.messageString = MovieType;

    return View("Information");

}
```

Navigate back to the test page and select the **HTML SelectList** link. The HTML page renders a select element similar to the simple ASP.NET MVC test page. Right click the browser window and select **view source**. The HTML markup for the select list is essentially identical. Test the HTML page, it works like the ASP.NET MVC action method and view we previously tested.

Improving the Movie Select List with Enums

If the categories in your application are fixed and will not change, you can take advantage of enums to make your code more robust and simpler to extend. When you add a new category, the correct category value is generated. The avoids copy and paste errors when you add a new category but forget to update the category value.

Open the *Controllers\HomeController.cs* file and examine the following code:

```
public enum eMovieCategories { Action, Drama, Comedy, Science_Fiction };

private void SetViewBagMovieType(eMovieCategories selectedMovie) {

    IEnumerable<eMovieCategories> values =

                        Enum.GetValues(typeof(eMovieCategories))

                        .Cast<eMovieCategories>();

    IEnumerable<SelectListItem> items =

        from value in values

        select new SelectListItem

        {

            Text = value.ToString(),

            Value = value.ToString(),

            Selected = value == selectedMovie,

        };

    ViewBag.MovieType = items;

}

public ActionResult SelectCategoryEnum() {

    SetViewBagMovieType(eMovieCategories.Drama);

    return View("SelectCategory");

}
```

The enum `eMovieCategories` captures the four movie types. The `SetViewBagMovieType` method creates the **IEnumerable<SelectListItem >** from the `eMovieCategories` **enum**, and sets the `Selected` property from the `selectedMovie` parameter. The `SelectCategoryEnum` action method uses the same view as the `SelectCategory` action method.

Navigate to the Test page and click on the `Select Movie Category (Enum)` link. This time, instead of a value (number) being displayed, a string representing the enum is displayed.

Posting Enum Values

HTML Forms are typically used to post data to the server. The following code shows the `HTTP GET` and `HTTP POST` versions of the `SelectCategoryEnumPost` method.

```
public ActionResult SelectCategoryEnumPost() {

    SetViewBagMovieType(eMovieCategories.Comedy);

    return View();

}

[HttpPost]

public ActionResult SelectCategoryEnumPost(eMovieCategories MovieType) {

    ViewBag.messageString = MovieType.ToString() +

                            " val = " + (int)MovieType;

    return View("Information");

}
```

By passing a `eMovieCategories` enum to the `POST` method, we can extract both the enum value and the enum string. Run the sample and navigate to the Test page. Click on the `Select Movie Category(Enum Post)` link. Select a movie type and then hit the submit button. The display shows both the value and the name of the movie type.

Creating a Multiple Section Select Element

The ListBox HTML helper renders the HTML `<select>` element with the `multiple` attribute, which allows the users to make multiple selections. Navigate to the Test link, then select the **Multi Select Country** link. The rendered UI allows you to select multiple countries. In the image below, Canada and China are selected.

Examining the MultiSelectCountry Code

Examine the following code from the *Controllers\HomeController.cs* file.

```
private MultiSelectList GetCountries(string[] selectedValues) {

    List<Country> Countries = new List<Country>()

        {

            new Country() { ID = 1, Name= "United States" },

            new Country() { ID = 2, Name= "Canada" },

            new Country() { ID = 3, Name= "UK" },

            new Country() { ID = 4, Name= "China" },

            new Country() { ID = 5, Name= "Japan" }

        };

    return new MultiSelectList(Countries, "ID", "Name", selectedValues);

}

public ActionResult MultiSelectCountry() {

    ViewBag.Countrieslist = GetCountries(null);

    return View();

}
```

The `GetCountries` method creates a list of countries, then passes it to the `MultiSelectList` constructor. The `MultiSelectList` constructor overload used in the `GetCountries` method above takes four parameters:

```
public MultiSelectList(

    IEnumerable items,

    string dataValueField,

    string dataTextField,

    IEnumerable selectedValues

)
```

1. *items*: An IEnumerable containing the items in the list. In the example above, the list of Countries.
2. *dataValueField*: The name of the property in the **IEnumerable** list that contains the value. In the example above, the `ID` property.
3. *dataTextField*: The name of the property in the **IEnumerable** list that contains the information to display. In the example above, the `name` property.
4. *selectedValues*: The list of selected values.

In the example above, the `MultiSelectCountry` method passes a `null` value for the selected countries, so no countries are selected when the UI is displayed. The following code shows the Razor markup used to render the `MultiSelectCountry` view.

```
@{

    ViewBag.Title = "MultiSelect Country";

    Layout = "~/Views/Shared/_Simple_Layout.cshtml";

}

@if (ViewBag.YouSelected != null) {

    <div> You Selected:  @ViewBag.YouSelected</div>

}

@using (Html.BeginForm()) {

    <fieldset>

        <legend>Multi-Select Demo</legend>

        <div class="editor-field">

            @Html.ListBox("Countries", ViewBag.Countrieslist as MultiSelectList

            )

        </div>

        <p>

            <input type="submit" value="Save" />

        </p>

    </fieldset>

}
```

The HTML helper ListBox method used above take two parameters, the name of the property to model bind and the MultiSelectList containing the select options and values. The `ViewBag.YouSelected` code above is used to display the values of the countries you selected when you submit the form. Examine the HTTP POST overload of the `MultiSelectCountry` method.

```
[HttpPost]

public ActionResult MultiSelectCountry(FormCollection form) {

    ViewBag.YouSelected = form["Countries"];

    string selectedValues = form["Countries"];

    ViewBag.Countrieslist = GetCountries(selectedValues.Split(','));

    return View();

}
```

The `ViewBag.YouSelected` dynamic property contains the selected countries, obtained for the `Countries` entry in the form collection. In this version the GetCountries method is passed a list of the selected countries, so when the `MultiSelectCountry` view is displayed, the selected countries are selected in the UI.

Making a Select Element Friendly with the Harvest Chosen jQuery Plugin

The Harvest Chosen jQuery plugin can be added to an HTML <select> element to create a user friendly UI. The images below demonstrate the Harvest Chosen jQuery plugin with `MultiSelectCountry` view.

In the two images below, **Canada** is selected.

In the image above, Canada is selected, and it contains an **x** you can click to remove the selection. The image below shows Canada, China, and Japan selected.

Hooking up the Harvest Chosen jQuery Plugin

The following section is easier to follow if you have some experience with jQuery. If you have never used jQuery before, you might want to try one of the following jQuery tutorials.

- How jQuery Works by John Resig
- Getting Started with jQuery by Jörn Zaefferer
- Live Examples of jQuery by Cody Lindley

The Chosen plugin is included in the starter and completed sample projects that accompany this tutorial. For this tutorial you will only need to use jQuery to hook it up to the UI. To use the Harvest Chosen jQuery plugin in an ASP.NET MVC project, you must:

1. Download Chosen plugin from github. This step has been done for you.
2. Add the Chosen folder to your ASP.NET MVC project. Add the assets from the Chosen plugin you downloaded in the previous step to the Chosen folder. This step has been done for you.
3. Hook up the chosen plugin to the **DropDownList** or **ListBox** HTML helper.

Hooking up the Chosen Plugin to the MultiSelectCountry View.

Open the *Views\Home\MultiSelectCountry.cshtml* file and add an `htmlAttributes` parameter to the `Html.ListBox` . The parameter you will add contains a class name for the select list(`@class = "chzn-select"`). The completed code is shown below:

```
<div class="editor-field">

    @Html.ListBox("Countries", ViewBag.Countrieslist as MultiSelectList

     , new

     {

         @class = "chzn-select",

         data_placeholder = "Choose  Countries..."

     }

    )

</div>
```

In the code above, we are adding the HTML attribute and attribute value `class = "chzn-select"`. The @ character

preceding class has nothing to do with the Razor view engine. `class` is a C# keyword. C# keywords cannot be used as identifiers unless they include @ as a prefix. In the example above, `@class` is a valid identifier but **class** is not because **class** is a keyword.

Add references to the *Chosen/chosen.jquery.js* and *Chosen/chosen.css* files. The *Chosen/chosen.jquery.js* and implements the functionally of the Chosen plugin. The *Chosen/chosen.css* file provides the styling. Add these references to the bottom of the *Views\Home\MultiSelectCountry.cshtml* file. The following code shows how to reference the Chosen plugin.

```
<script src="@Url.Content("~/Chosen/chosen.jquery.js")" type="text/javascript"></script><script
src="@Url.Content("~/Chosen/chosen.jquery.js")" type="text/javascript"></script>

<link href="@Url.Content("~/Chosen/chosen.css")" rel="stylesheet"  type="text/css" />
```

Activate the Chosen plugin using the class name used in the **Html.ListBox** code. In the example above, the class name is `chzn-select`. Add the following line to the bottom of the *Views\Home\MultiSelectCountry.cshtml* view file. This line activates the Chosen plugin.

```
<script >    $(".chzn-select").chosen(); </script>  @*Hookup Chosen Plugin*@
```

The following line is the syntax to call the jQuery ready function, which selects the DOM element with class name `chzn-select`.

```
$(".chzn-select")
```

The wrapped set returned from the above call then applies the chosen method (`.chosen();`), which hooks up the Chosen plugin.

The following code shows the completed *Views\Home\MultiSelectCountry.cshtml* view file.

```
@{

    ViewBag.Title = "MultiSelect Country";

    Layout = "~/Views/Shared/_Simple_Layout.cshtml";

}

@if (ViewBag.YouSelected != null) {

    <div> You Selected:  @ViewBag.YouSelected</div>

}

@using (Html.BeginForm()) {

    <fieldset>

        <legend>Multi-Select Demo</legend>

<div class="editor-field">

    @Html.ListBox("Countries", ViewBag.Countrieslist as MultiSelectList

     , new

     {

         @class = "chzn-select"

     }

    )

</div>

        <p>

            <input type="submit" value="Save" />

        </p>

    </fieldset>

}

<script src="@Url.Content("~/Chosen/chosen.jquery.js")" type="text/javascript"></script>

<link href="@Url.Content("~/Chosen/chosen.css")" rel="stylesheet"  type="text/css" />

<script >    $(".chzn-select").chosen(); </script> @*Hookup Chosen Plugin*@
```

Run the application and navigate to the `MultiSelectCountry` view. Try adding and deleting countries. The sample download provided also contains a `MultiCountryVM` method and view that implements the MultiSelectCountry functionality using a view model instead of a **ViewBag**.

In the next section you'll see how the ASP.NET MVC scaffolding mechanism works with the **DropDownList** helper.

NEXT

Examining how ASP.NET MVC scaffolds the DropDownList Helper

2/20/2020 • 11 minutes to read • Edit Online

by Rick Anderson

In **Solution Explorer**, right-click the *Controllers* folder and then select **Add Controller**. Name the controller **StoreManagerController**. Set the options for the **Add Controller** dialog as shown in the image below.

Edit the *StoreManager\Index.cshtml* view and remove `AlbumArtUrl`. Removing `AlbumArtUrl` will make the presentation more readable. The completed code is shown below.

```
@model IEnumerable<MvcMusicStore.Models.Album>

@{

    ViewBag.Title = "Index";

}

<h2>Index</h2>

<p>

    @Html.ActionLink("Create New", "Create")

</p>

<table>

    <tr>

        <th>

            Genre

        </th>
```

```
        <th>
            Artist
        </th>
        <th>
            Title
        </th>
        <th>
            Price
        </th>
        <th></th>
    </tr>
@foreach (var item in Model) {
    <tr>
        <td>
            @Html.DisplayFor(modelItem => item.Genre.Name)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Artist.Name)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Title)
        </td>
        <td>
            @Html.DisplayFor(modelItem => item.Price)
        </td>
        <td>
            @Html.ActionLink("Edit", "Edit", new { id=item.AlbumId }) |
            @Html.ActionLink("Details", "Details", new { id=item.AlbumId }) |
            @Html.ActionLink("Delete", "Delete", new { id=item.AlbumId })
        </td>
    </tr>
}
</table>
```

Open the *Controllers\StoreManagerController.cs* file and find the `Index` method. Add the `OrderBy` clause so the

albums will be sorted by price. The complete code is shown below.

```
public ViewResult Index()
{

    var albums = db.Albums.Include(a => a.Genre).Include(a => a.Artist)

        .OrderBy(a => a.Price);

    return View(albums.ToList());

}
```

Sorting by price will make it easier to test changes to the database. When you are testing the edit and create methods, you can use a low price so the saved data will appear first.

Open the *StoreManager\Edit.cshtml* file. Add the following line just after the legend tag.

```
@Html.HiddenFor(model => model.AlbumId)
```

The following code shows the context of this change:

```
@using (Html.BeginForm()) {

    @Html.ValidationSummary(true)

    <fieldset>

        <legend>Album</legend>

        @Html.HiddenFor(model => model.AlbumId)

        <div class="editor-label">

            @Html.LabelFor(model => model.GenreId, "Genre")

        </div>

        <div class="editor-field">

            @Html.DropDownList("GenreId", String.Empty)

            @Html.ValidationMessageFor(model => model.GenreId)

        </div>

        <!-- Items removed for brevity. -->

}
```

The `AlbumId` is required to make changes to an album record.

Press CTRL+F5 to run the application. Select to the **Admin** link, then select the **Create New** link to create a new album. Verify the album information was saved. Edit an album and verify the changes you made are persisted.

The Album Schema

The `StoreManager` controller created by the MVC scaffolding mechanism allows CRUD (Create, Read, Update, Delete) access to the albums in the music store database. The schema for album information is shown below:

The `Albums` table does not store the album genre and description, it stores a foreign key to the `Genres` table. The `Genres` table contains the genre name and description. Likewise, the `Albums` table doesn't contain the album artists name, but a foreign key to the `Artists` table. The `Artists` table contains the artist's name. If you examine the data in the `Albums` table, you can see each row contains a foreign key to the `Genres` table and a foreign key to the `Artists` table. The image below show some table data from the `Albums` table.

The HTML Select Tag

The HTML `<select>` element (created by the HTML DropDownList helper) is used to display a complete list of values (such as the list of genres). For edit forms, when the current value is known, the select list can display the current value. We saw this previously when we set the selected value to **Comedy**. The select list is ideal for displaying category or foreign key data. The `<select>` element for the Genre foreign key displays the list of possible genre names, but when you save the form the Genre property is updated with the Genre foreign key value, not the displayed genre name. In the image below, the genre selected is **Disco** and the artist is **Donna Summer**.

Examining the ASP.NET MVC Scaffolded Code

Open the *Controllers\StoreManagerController.cs* file and find the `HTTP GET Create` method.

```
public ActionResult Create()

{

    ViewBag.GenreId = new SelectList(db.Genres, "GenreId", "Name");

    ViewBag.ArtistId = new SelectList(db.Artists, "ArtistId", "Name");

    return View();

}
```

The `Create` method adds two SelectList objects to the `ViewBag`, one to contain the genre information, and one to contain the artist information. The SelectList constructor overload used above takes three arguments:

```
public SelectList(

    IEnumerable items,

    string dataValueField,

    string dataTextField

)
```

1. *items*: An IEnumerable containing the items in the list. In the example above, the list of genres returned by `db.Genres`.
2. *dataValueField*: The name of the property in the **IEnumerable** list that contains the key value. In the example

above, `GenreId` and `ArtistId`.

3. *dataTextField*: The name of the property in the **IEnumerable** list that contains the information to display. In both the artists and genre table, the `name` field is used.

Open the *Views\StoreManager\Create.cshtml* file and examine the `Html.DropDownList` helper markup for the genre field.

```
@model MvcMusicStore.Models.Album

@*        Markup removed for clarity.*@

@Html.DropDownList("GenreId", String.Empty)
```

The first line shows that the create view takes an `Album` model. In the `Create` method shown above, no model was passed, so the view gets a **null** `Album` model. At this point we are creating a new album so we don't have any `Album` data for it.

The Html.DropDownList overload shown above takes the name of the field to bind to the model. It also uses this name to look for a **ViewBag** object containing a SelectList object. Using this overload, you are required to name the **ViewBag SelectList** object `GenreId`. The second parameter (`String.Empty`) is the text to display when no item is selected. This is exactly what we want when creating a new album. If you removed the second parameter and used the following code:

```
@Html.DropDownList("GenreId")
```

The select list would default to the first element, or Rock in our sample.

Examining the `HTTP POST Create` method.

```
//

// POST: /StoreManager/Create

[HttpPost]

public ActionResult Create(Album album)

{

    if (ModelState.IsValid)

    {

        db.Albums.Add(album);

        db.SaveChanges();

        return RedirectToAction("Index");

    }

    ViewBag.GenreId = new SelectList(db.Genres, "GenreId", "Name",

        album.GenreId);

    ViewBag.ArtistId = new SelectList(db.Artists, "ArtistId", "Name",

        album.ArtistId);

    return View(album);

}
```

This overload of the `Create` method takes an `album` object, created by the ASP.NET MVC model binding system from the form values posted. When you submit a new album, if model state is valid and there are no database errors, the new album is added the database. The following image shows the creation of a new album.

You can use the fiddler tool to examine the posted form values that ASP.NET MVC model binding uses to create the album object.

Refactoring the ViewBag SelectList Creation

Both the `Edit` methods and the `HTTP POST Create` method have identical code to set up the **SelectList** in the **ViewBag**. In the spirit of DRY, we will refactor this code. We'll make use of this refactored code later.

Create a new method to add a genre and artist **SelectList** to the **ViewBag**.

```
private void SetGenreArtistViewBag(int? GenreID = null, int? ArtistID = null) {

    if (GenreID == null)

        ViewBag.GenreId = new SelectList(db.Genres, "GenreId", "Name");

    else

        ViewBag.GenreId = new SelectList(db.Genres.ToArray(), "GenreId", "Name", GenreID);

    if (ArtistID == null)

        ViewBag.ArtistId = new SelectList(db.Artists, "ArtistId", "Name");

    else

        ViewBag.ArtistId = new SelectList(db.Artists, "ArtistId", "Name", ArtistID);

}
```

Replace the two lines setting the `ViewBag` in each of the `Create` and `Edit` methods with a call to the `SetGenreArtistViewBag` method. The completed code is shown below.

```
//

// GET: /StoreManager/Create

public ActionResult Create() {

    SetGenreArtistViewBag();

    return View();

}

//

// POST: /StoreManager/Create

[HttpPost]

public ActionResult Create(Album album) {

    if (ModelState.IsValid) {

        db.Albums.Add(album);

        db.SaveChanges();

        return RedirectToAction("Index");

    }

    SetGenreArtistViewBag(album.GenreId, album.ArtistId);

    return View(album);

}

//

// GET: /StoreManager/Edit/5

public ActionResult Edit(int id) {
```

```
public ActionResult Edit(int id) {

    Album album = db.Albums.Find(id);

    SetGenreArtistViewBag(album.GenreId, album.ArtistId);

    return View(album);

}

//

// POST: /StoreManager/Edit/5

[HttpPost]

public ActionResult Edit(Album album) {

    if (ModelState.IsValid) {

        db.Entry(album).State = EntityState.Modified;

        db.SaveChanges();

        return RedirectToAction("Index");

    }

    SetGenreArtistViewBag(album.GenreId, album.ArtistId);

    return View(album);

}
```

Create a new album and edit an album to verify the changes work.

Explicitly Passing the SelectList to the DropDownList

The create and edit views created by the ASP.NET MVC scaffolding use the following **DropDownList** overload:

```
public static MvcHtmlString DropDownList(

    this HtmlHelper htmlHelper,

    string name,         // The name of the ViewModel property to bind.

    string optionLabel   // The string added to the top of the list

                         // typically  String.Empty or "Select a Genre"

)
```

The `DropDownList` markup for the create view is shown below.

```
@Html.DropDownList("GenreId", String.Empty)
```

Because the `ViewBag` property for the `SelectList` is named `GenreId`, the **DropDownList** helper will use the `GenreId` **SelectList** in the **ViewBag**. In the following **DropDownList** overload, the `SelectList` is explicitly passed in.

```
public static MvcHtmlString DropDownList(

    this HtmlHelper htmlHelper,

    string name,            // The name of the ViewModel property to bind.

    IEnumerable selectList  // The SelectList

)
```

Open the *Views\StoreManager\Edit.cshtml* file, and change the **DropDownList** call to explicitly pass in the **SelectList**, using the overload above. Do this for the Genre category. The completed code is shown below:

```
@Html.DropDownList("GenreId", ViewBag.GenreId as SelectList)
```

Run the application and click the **Admin** link, then navigate to a Jazz album and select the **Edit** link.

Instead of showing Jazz as the currently selected genre, Rock is displayed. When the string argument (the property to bind) and the **SelectList** object have the same name, the selected value is not used. When there is no selected value provided, browsers default to the first element in the **SelectList**(which is **Rock** in the example above). This is a known limitation of the **DropDownList** helper.

Open the *Controllers\StoreManagerController.cs* file and change the **SelectList** object names to `Genres` and `Artists`. The completed code is shown below:

```
private void SetGenreArtistViewBag(int? GenreID = null, int? ArtistID = null) {
    if (GenreID == null)

        ViewBag.Genres = new SelectList(db.Genres, "GenreId", "Name");

    else

        ViewBag.Genres = new SelectList(db.Genres.ToArray(), "GenreId", "Name", GenreID);

    if (ArtistID == null)

        ViewBag.Artists = new SelectList(db.Artists, "ArtistId", "Name");

    else

        ViewBag.Artists = new SelectList(db.Artists, "ArtistId", "Name", ArtistID);

}
```

The names Genres and Artists are better names for the categories, as they contain more than just the ID of each category. The refactoring we did earlier paid off. Instead of changing the **ViewBag** in four methods, our changes were isolated to the `SetGenreArtistViewBag` method.

Change the **DropDownList** call in the create and edit views to use the new **SelectList** names. The new markup for the edit view is shown below:

```
<div class="editor-label">

    @Html.LabelFor(model => model.GenreId, "Genre")

</div>

<div class="editor-field">

    @Html.DropDownList("GenreId", ViewBag.Genres as SelectList)

    @Html.ValidationMessageFor(model => model.GenreId)

</div>

<div class="editor-label">

    @Html.LabelFor(model => model.ArtistId, "Artist")

</div>

<div class="editor-field">

    @Html.DropDownList("ArtistId", ViewBag.Artists as SelectList)

    @Html.ValidationMessageFor(model => model.ArtistId)

</div>
```

The Create view requires an empty string to prevent the first item in the SelectList from being displayed.

```
<div class="editor-label">

    @Html.LabelFor(model => model.GenreId, "Genre" )

</div>

<div class="editor-field">

    @Html.DropDownList("GenreId", ViewBag.Genres as SelectList, String.Empty)

    @Html.ValidationMessageFor(model => model.GenreId)

</div>

<div class="editor-label">

    @Html.LabelFor(model => model.ArtistId, "Artist")

</div>

<div class="editor-field">

    @Html.DropDownList("ArtistId", ViewBag.Artists as SelectList, String.Empty)

    @Html.ValidationMessageFor(model => model.ArtistId)

</div>
```

Create a new album and edit an album to verify the changes work. Test the edit code by selecting an album with a genre other than Rock.

Using a View Model with the DropDownList Helper

Create a new class in the ViewModels folder named `AlbumSelectListViewModel`. Replace the code in the `AlbumSelectListViewModel` class with the following:

```
using MvcMusicStore.Models;

using System.Web.Mvc;

using System.Collections;

namespace MvcMusicStore.ViewModels {

    public class AlbumSelectListViewModel {

        public Album Album { get; private set; }

        public SelectList Artists { get; private set; }

        public SelectList Genres { get; private set; }

        public AlbumSelectListViewModel(Album album,

                                        IEnumerable artists,

                                        IEnumerable genres) {

            Album = album;

            Artists = new SelectList(artists, "ArtistID", "Name", album.ArtistId);

            Genres = new SelectList(genres, "GenreID", "Name", album.GenreId);

        }

    }

}
```

The `AlbumSelectListViewModel` constructor takes an album, a list of artists and genres and creates an object containing the album and a `SelectList` for genres and artists.

Build the project so the `AlbumSelectListViewModel` is available when we create a view in the next step.

Add an `EditVM` method to the `StoreManagerController`. The completed code is shown below.

```
//

// GET: /StoreManager/EditVM/5

public ActionResult EditVM(int id) {

    Album album = db.Albums.Find(id);

    if (album == null)

        return HttpNotFound();

    AlbumSelectListViewModel aslvm = new AlbumSelectListViewModel(album, db.Artists, db.Genres);

    return View(aslvm);

}
```

Right click `AlbumSelectListViewModel`, select **Resolve**, then **using MvcMusicStore.ViewModels;**.

Alternatively, you can add the following using statement:

```
using MvcMusicStore.ViewModels;
```

Right click `EditVM` and select **Add View**. Use the options shown below.

Select **Add**, then replace the contents of the *Views\StoreManager\EditVM.cshtml* file with the following:

```
@model MvcMusicStore.ViewModels.AlbumSelectListViewModel

@{

    ViewBag.Title = "EditVM";

}

<h2>Edit VM</h2>

@using (Html.BeginForm("Edit","StoreManager",FormMethod.Post)) {

    @Html.ValidationSummary(true)

    <fieldset>

        <legend>Album</legend>
```

```
        @Html.HiddenFor(model => model.Album.AlbumId )

        <div class="editor-label">

            @Html.LabelFor(model => model.Album.GenreId, "Genre")

        </div>

        <div class="editor-field">

            @Html.DropDownList("Album.GenreId", Model.Genres)

            @Html.ValidationMessageFor(model => model.Album.GenreId)

        </div>

        <div class="editor-label">

            @Html.LabelFor(model => model.Album.ArtistId, "Artist")

        </div>

        <div class="editor-field">

            @Html.DropDownList("Album.ArtistId", Model.Artists)

            @Html.ValidationMessageFor(model => model.Album.ArtistId)

        </div>

        <div class="editor-label">

            @Html.LabelFor(model => model.Album.Title)

        </div>

        <div class="editor-field">

            @Html.EditorFor(model => model.Album.Title)

            @Html.ValidationMessageFor(model => model.Album.Title)

        </div>

        <div class="editor-label">

            @Html.LabelFor(model => model.Album.Price)

        </div>

        <div class="editor-field">

            @Html.EditorFor(model => model.Album.Price)

            @Html.ValidationMessageFor(model => model.Album.Price)

        </div>

        <div class="editor-label">

            @Html.LabelFor(model => model.Album.AlbumArtUrl)

        </div>

        <div class="editor-field">

            @Html.EditorFor(model => model.Album.AlbumArtUrl)
```

```
            @Html.ValidationMessageFor(model => model.Album.AlbumArtUrl)

        </div>

        <p>

            <input type="submit" value="Save" />

        </p>

    </fieldset>

}

<div>

    @Html.ActionLink("Back to List", "Index")

</div>
```

The `EditVM` markup is very similar to the original `Edit` markup with the following exceptions.

- Model properties in the `Edit` view are of the form `model.property` (for example, `model.Title`). Model properties in the `EditVm` view are of the form `model.Album.property` (for example, `model.Album.Title`). That's because the `EditVM` view is passed a container for an `Album` , not an `Album` as in the `Edit` view.
- The **DropDownList** second parameter comes from the view model, not the **ViewBag**.
- The **BeginForm** helper in the `EditVM` view explicitly posts back to the `Edit` action method. By posting back to the `Edit` action, we don't have to write an `HTTP POST EditVM` action and can reuse the `HTTP POST` `Edit` action.

Run the application and edit an album. Change the URL to use `EditVM` . Change a field and hit the **Save** button to verify the code is working.

Which Approach Should You Use?

All three approaches shown are acceptable. Many developers prefer to explicitly pass the `SelectList` to the

`DropDownList` using the `ViewBag`. This approach has the added advantage of giving you the flexibility of using a more appropriate name for the collection. The one caveat is you cannot name the `ViewBag SelectList` object the same name as the model property.

Some developers prefer the ViewModel approach. Others consider the more verbose markup and generated HTML of the ViewModel approach a disadvantage.

In this section we have learned three approaches to using the **DropDownList** with category data. In the next section, we'll show how to add a new category.

Adding a New Category to the DropDownList using jQuery UI

2/20/2020 • 6 minutes to read • Edit Online

by Rick Anderson

The HTML `Select` tag is ideal for presenting a list of fixed category data, but often times you need to add a new category. Suppose we want to add the genre "Opera" to the categories in our database? In this section, we will use jQuery UI to add a dialog box we can use to add a new category. The image below shows how the UI will present in the browser.

When a user selects the **Add New Genre** link, a pop-up dialog box prompts the user for a new genre name (and optionally a description). The image below show the **Add Genre** pop-up dialog.

When a new genre name is entered and the **Save** button is pushed, the following happens:

1. An AJAX call posts the data to the Create method of the Genre Controller, which saves the new genre to the database and returns the new genre information (genre name and ID) as JSON.
2. JavaScript adds the new genre data to the select list.
3. JavaScript makes the new genre the selected item.

   In the image below, **Opera** was added to the database and selected in the **Genre** drop down list.

Open the *Views\StoreManager\Create.cshtml* file and replace the genre markup with the following the following code:

```
<div class="editor-field ui-widget">

     @Html.Partial("_ChooseGenre")

</div>
```

The `_ChooseGenre` partial view will contain all the logic to hook up the JavaScript and jQuery used to implement the add new genre feature. Once we have completed the code it will be simple to do the same with the artist UI.

In Solution Explorer, right click the *Views\StoreManager* folder and select **Add**, then **View**. In the **View name** input, enter `_ChooseGenre` then select **Add**. Replace the markup in the *Views\StoreManager_ChooseGenre.cshtml* file with the following:

```
@model MvcMusicStore.Models.Album

<div class="editor-label">

    @Html.LabelFor(model => model.GenreId, "Genre" )

</div>

@Html.DropDownList("GenreId", ViewBag.Genres as SelectList, String.Empty)

<a class="button" href="@Url.Content("~/Genre/Create")"

    id="genreAddLink">Add New Genre</a>

@Html.ValidationMessageFor(model => model.GenreId)

<div id="genreDialog" class="hidden">

</div>

<script src="@Url.Content( "~/Scripts/ui/jquery.ui.combobox.js" )"></script>

<script src="@Url.Content("~/Scripts/chooseGenre.js")"></script>
```

The first line declares that we are passing in an `Album` as our model, exactly the same model statement found in the Create view. The next few lines are the **Label** helper markup. The next line is the **DropDownList** helper call, exactly the same as in the original Create view. The next line adds a link with the name `Add New Genre`, and styles it like a button. The line containing `ValidationMessageFor` is copied directly from the Create view. The following lines:

```
<div id="genreDialog" class="hidden">

</div>
```

creates a hidden div, with the ID of `genreDialog`. We will use jQuery to hook up our **Add Genre** dialog box with the ID `genreDialog` in this div. The last two script tags contain links to the JavaScript files we will use to implement the add new genre feature. The */Scripts/chooseGenre.js* file is provided for you in the project, we will examine it later in the tutorial.

Run the application and click on the **Add New Genre** button. In the **Add Genre** dialog box, enter **Opera** in the **Name** input box.

Click the **Save** button. An AJAX call creates the Opera category and then populates the dropdown list with Opera, and sets Opera as the selected genre.

Enter an artist, title and price, then select the **Create** button. If you enter a price less than $8.99, the new album will appear at the top of the Index view. Verify the new album entry was saved in the database.

Try creating a new genre with only one letter. The following code in the *Models\Genre.cs* file sets the minimum and maximum length of the genre name.

```
[StringLength(20, MinimumLength = 2)]
public string Name { get; set; }
```

Client side validation reports you must enter a string between 2 and 20 characters.

Examining How a New Genre is Added to the Database and the Select List.

Open the *Scripts\chooseGenre.js* file and examine the code.

```
$(function () {

    $('#genreDialog').dialog({

        autoOpen: false,

        width: 400,

        height: 300,

        modal: true,

        title: 'Add Genre',

        buttons: {

            'Save': function () {

                // Omitted

            },

            'Cancel': function () {

                $(this).dialog('close');

            }

        }

    });
```

The second line uses the ID `genreDialog` to create a dialog box on the div tag in the *Views\StoreManager_ChooseGenre.cshtml* file. Most of the named parameters are self explanatory. The `autoOpen` parameter is set to false, selecting the **Create Genre** button will open the dialogue explicitly (this is described latter on). The dialog has two buttons, **Save** and **Cancel**. The **Cancel** button closes the dialog. The following code shows the **Save** button function.

```
'Save': function () {

    var createGenreForm = $('#createGenreForm');

    if (createGenreForm.valid()) {

        $.post(createGenreForm.attr('action'), createGenreForm.serialize(), function (data) {

            if (data.Error != '') {

                alert(data.Error);

            }

            else {

                // Add the new genre to the dropdown list and select it

                $('#GenreId').append(

                        $('<option></option>')

                            .val(data.Genre.GenreId)

                            .html(data.Genre.Name)

                            .prop('selected', true)  // Selects the new Genre in the DropDown LB

                    );

                $('#genreDialog').dialog('close');

            }

        });

    }

},
```

The `var createGenreForm` is selected from the `createGenreForm` ID. The `createGenreForm` ID was set in the following code found in the *Views\Genre_CreateGenre.cshtml* file.

```
@model MvcMusicStore.Models.Genre

@using (Html.BeginForm("Create", "Genre", FormMethod.Post, new { id = "createGenreForm" }))

{

    @*Omitted for clarity.*@

}
```

The Html.BeginForm helper overload used in the *Views\Genre_CreateGenre.cshtml* file generates HTML with an action attribute containing the URL to submit the form. You can see this by displaying the create album page in a browser and selecting show source in the browser. The following markup shows the generated HTML containing the form tag.

```
<form action="/StoreManager/Create" method="post">
```

The jQuery `$.post` line makes an AJAX call to the action attribute (`/StoreManager/Create`) and passes in the data

from the **Create Genre** dialog box. The data consists of the name for the new genre and an optional description. If the AJAX call is successful, the new genre name and value are added to the Select markup, and the new genre is set to the selected value. Because this is dynamically generated markup, you can't see the new select option by viewing the source in the browser. You can see the new HTML with the IE 9 F12 developer tools. To view the new select option, in Internet Explorer 9, hit the F12 key to start the F12 developer tools. Navigate to the Create page and add a new genre so the new genre is selected in the genre select list. In the F12 developer tools:

1. Select the HTML tab.
2. Hit the refresh icon.

3. In the search box, enter GenreID.
4. Using the next icon,

navigate to the following select tag:

```
<select name="GenreId" id="GenreId" >
```

5. Expand the last option value.

The following code in the *Scripts\chooseGenre.js* file shows the how the **Add New Genre** button gets connected

to the click event, and how the **Add New Genre** dialog box is created.

```
$('#genreAddLink').click(function () {

    var createFormUrl = $(this).attr('href');

    $('#genreDialog').html('')

    .load(createFormUrl, function () {

        // The createGenreForm is loaded on the fly using jQuery load.

        // In order to have client validation working it is necessary to tell the

        // jQuery.validator to parse the newly added content

        jQuery.validator.unobtrusive.parse('#createGenreForm');

        $('#genreDialog').dialog('open');

    });

    return false;

});
```

The first line creates a click function attached to the **Add New Genre** button. The following markup from the Views\StoreManager_ChooseGenre.cshtml file shows how the **Add New Genre** button is created:

```
<a class="button" href="@Url.Content("~/Genre/Create")"

    id="genreAddLink">Add New Genre</a>
```

The load method creates and opens the Add Genre dialog and calls the jQuery `parse` method so client validation occurs on data entered in the dialog.

In this section you have learned how to create a dialog that can be used to add new category data to a select list. You can follow the same procedure to create UI to add a new artist to the artist select list. This tutorial has given an overview of working with the ASP.NET MVC HTML helper **DropDownList**. For additional information on working with the **DropDownList**, see the addition references section below. Please let us know if this tutorial has been helpful.

> Learn about the differences between ASP.NET MVC application and ASP.NET Web Forms applications. Learn how to decide when to build an ASP.NET MVC application.

The Model-View-Controller (MVC) architectural pattern separates an application into three main components: the model, the view, and the controller. The ASP.NET MVC framework provides an alternative to the ASP.NET Web Forms pattern for creating MVC-based Web applications. The ASP.NET MVC framework is a lightweight, highly testable presentation framework that (as with Web Forms-based applications) is integrated with existing ASP.NET features, such as master pages and membership-based authentication. The MVC framework is defined in the **System.Web.Mvc** namespace and is a fundamental, supported part of the **System.Web** namespace.

MVC is a standard design pattern that many developers are familiar with. Some types of Web applications will benefit from the MVC framework. Others will continue to use the traditional ASP.NET application pattern that is based on Web Forms and postbacks. Other types of Web applications will combine the two approaches; neither approach excludes the other.

The MVC framework includes the following components:

Figure 01: Invoking a controller action that expects a parameter value (Click to view full-size image)

- **Models**. Model objects are the parts of the application that implement the logic for the application s data domain. Often, model objects retrieve and store model state in a database. For example, a Product object might retrieve information from a database, operate on it, and then write updated information back to a Products table in SQL Server.

In small applications, the model is often a conceptual separation instead of a physical one. For example, if the application only reads a data set and sends it to the view, the application does not have a physical model layer and associated classes. In that case, the data set takes on the role of a model object.

- **Views**. Views are the components that display the application s user interface (UI). Typically, this UI is created from the model data. An example would be an edit view of a Products table that displays text boxes, drop-down lists, and check boxes based on the current state of a Products object.
- **Controllers**. Controllers are the components that handle user interaction, work with the model, and

ultimately select a view to render that displays UI. In an MVC application, the view only displays information; the controller handles and responds to user input and interaction. For example, the controller handles query-string values, and passes these values to the model, which in turn queries the database by using the values.

The MVC pattern helps you create applications that separate the different aspects of the application (input logic, business logic, and UI logic), while providing a loose coupling between these elements. The pattern specifies where each kind of logic should be located in the application. The UI logic belongs in the view. Input logic belongs in the controller. Business logic belongs in the model. This separation helps you manage complexity when you build an application, because it enables you to focus on one aspect of the implementation at a time. For example, you can focus on the view without depending on the business logic.

In addition to managing complexity, the MVC pattern makes it easier to test applications than it is to test a Web Forms-based ASP.NET Web application. For example, in a Web Forms-based ASP.NET Web application, a single class is used both to display output and to respond to user input. Writing automated tests for Web Forms-based ASP.NET applications can be complex, because to test an individual page, you must instantiate the page class, all its child controls, and additional dependent classes in the application. Because so many classes are instantiated to run the page, it can be hard to write tests that focus exclusively on individual parts of the application. Tests for Web Forms-based ASP.NET applications can therefore be more difficult to implement than tests in an MVC application. Moreover, tests in a Web Forms-based ASP.NET application require a Web server. The MVC framework decouples the components and makes heavy use of interfaces, which makes it possible to test individual components in isolation from the rest of the framework.

The loose coupling between the three main components of an MVC application also promotes parallel development. For instance, one developer can work on the view, a second developer can work on the controller logic, and a third developer can focus on the business logic in the model.

Deciding When to Create an MVC Application

You must consider carefully whether to implement a Web application by using either the ASP.NET MVC framework or the ASP.NET Web Forms model. The MVC framework does not replace the Web Forms model; you can use either framework for Web applications. (If you have existing Web Forms-based applications, these continue to work exactly as they always have.)

Before you decide to use the MVC framework or the Web Forms model for a specific Web site, weigh the advantages of each approach.

Advantages of an MVC-Based Web Application

The ASP.NET MVC framework offers the following advantages:

- It makes it easier to manage complexity by dividing an application into the model, the view, and the controller.
- It does not use view state or server-based forms. This makes the MVC framework ideal for developers who want full control over the behavior of an application.
- It uses a Front Controller pattern that processes Web application requests through a single controller. This enables you to design an application that supports a rich routing infrastructure. For more information, see Front Controller on the MSDN Web site.
- It provides better support for test-driven development (TDD).
- It works well for Web applications that are supported by large teams of developers and Web designers who need a high degree of control over the application behavior.

Advantages of a Web Forms-Based Web Application

The Web Forms-based framework offers the following advantages:

- It supports an event model that preserves state over HTTP, which benefits line-of-business Web application development. The Web Forms-based application provides dozens of events that are supported in hundreds of

server controls.

- It uses a Page Controller pattern that adds functionality to individual pages. For more information, see Page Controller on the MSDN Web site.
- It uses view state or server-based forms, which can make managing state information easier.
- It works well for small teams of Web developers and designers who want to take advantage of the large number of components available for rapid application development.
- In general, it is less complex for application development, because the components (the **Page** class, controls, and so on) are tightly integrated and usually require less code than the MVC model.

Features of the ASP.NET MVC Framework

The ASP.NET MVC framework provides the following features:

- Separation of application tasks (input logic, business logic, and UI logic), testability, and test-driven development (TDD) by default. All core contracts in the MVC framework are interface-based and can be tested by using mock objects, which are simulated objects that imitate the behavior of actual objects in the application. You can unit-test the application without having to run the controllers in an ASP.NET process, which makes unit testing fast and flexible. You can use any unit-testing framework that is compatible with the .NET Framework.
- An extensible and pluggable framework. The components of the ASP.NET MVC framework are designed so that they can be easily replaced or customized. You can plug in your own view engine, URL routing policy, action-method parameter serialization, and other components. The ASP.NET MVC framework also supports the use of Dependency Injection (DI) and Inversion of Control (IOC) container models. DI allows you to inject objects into a class, instead of relying on the class to create the object itself. IOC specifies that if an object requires another object, the first objects should get the second object from an outside source such as a configuration file. This makes testing easier.
- A powerful URL-mapping component that lets you build applications that have comprehensible and searchable URLs. URLs do not have to include file-name extensions, and are designed to support URL naming patterns that work well for search engine optimization (SEO) and representational state transfer (REST) addressing.
- Support for using the markup in existing ASP.NET page (.aspx files), user control (.ascx files), and master page (.master files) markup files as view templates. You can use existing ASP.NET features with the ASP.NET MVC framework, such as nested master pages, in-line expressions (<%= %>), declarative server controls, templates, data-binding, localization, and so on.
- Support for existing ASP.NET features. ASP.NET MVC lets you use features such as forms authentication and Windows authentication, URL authorization, membership and roles, output and data caching, session and profile state management, health monitoring, the configuration system, and the provider architecture.

Understanding the ASP.NET MVC Execution Process

4/10/2020 • 2 minutes to read • Edit Online

by Microsoft

> Learn how the ASP.NET MVC framework processes a browser request step-by-step.

Requests to an ASP.NET MVC-based Web application first pass through the **UrlRoutingModule** object, which is an HTTP module. This module parses the request and performs route selection. The **UrlRoutingModule** object selects the first route object that matches the current request. (A route object is a class that implements **RouteBase**, and is typically an instance of the **Route** class.) If no routes match, the **UrlRoutingModule** object does nothing and lets the request fall back to the regular ASP.NET or IIS request processing.

From the selected **Route** object, the **UrlRoutingModule** object obtains the **IRouteHandler** object that is associated with the **Route** object. Typically, in an MVC application, this will be an instance of **MvcRouteHandler**. The **IRouteHandler** instance creates an **IHttpHandler** object and passes it the **IHttpContext** object. By default, the **IHttpHandler** instance for MVC is the **MvcHandler** object. The **MvcHandler** object then selects the controller that will ultimately handle the request.

> **NOTE**
>
> When an ASP.NET MVC Web application runs in IIS 7.0, no file name extension is required for MVC projects. However, in IIS 6.0, the handler requires that you map the .mvc file name extension to the ASP.NET ISAPI DLL.

The module and handler are the entry points to the ASP.NET MVC framework. They perform the following actions:

- Select the appropriate controller in an MVC Web application.
- Obtain a specific controller instance.
- Call the controller's **Execute** method.

The following lists the stages of execution for an MVC Web project:

- Receive first request for the application
  - In the Global.asax file, **Route** objects are added to the **RouteTable** object.
- Perform routing
  - The **UrlRoutingModule** module uses the first matching **Route** object in the **RouteTable** collection to create the **RouteData** object, which it then uses to create a **RequestContext** (**IHttpContext**) object.
- Create MVC request handler
  - The **MvcRouteHandler** object creates an instance of the **MvcHandler** class and passes it the **RequestContext** instance.
- Create controller
  - The **MvcHandler** object uses the **RequestContext** instance to identify the **IControllerFactory** object (typically an instance of the **DefaultControllerFactory** class) to create the controller instance with.
- Execute controller - The **MvcHandler** instance calls the controller s **Execute** method. |
- Invoke action
  - Most controllers inherit from the **Controller** base class. For controllers that do so, the

ControllerActionInvoker object that is associated with the controller determines which action method of the controller class to call, and then calls that method.

- Execute result
  - A typical action method might receive user input, prepare the appropriate response data, and then execute the result by returning a result type. The built-in result types that can be executed include the following: **ViewResult** (which renders a view and is the most-often used result type), **RedirectToRouteResult**, **RedirectResult**, **ContentResult**, **JsonResult**, and **EmptyResult**.

Understanding Models, Views, and Controllers (C#)

9/16/2020 • 9 minutes to read • Edit Online

by Stephen Walther

> Confused about Models, Views, and Controllers? In this tutorial, Stephen Walther introduces you to the different parts of an ASP.NET MVC application.

This tutorial provides you with a high-level overview of ASP.NET MVC models, views, and controllers. In other words, it explains the M', V', and C' in ASP.NET MVC.

After reading this tutorial, you should understand how the different parts of an ASP.NET MVC application work together. You should also understand how the architecture of an ASP.NET MVC application differs from an ASP.NET Web Forms application or Active Server Pages application.

The Sample ASP.NET MVC Application

The default Visual Studio template for creating ASP.NET MVC Web Applications includes an extremely simple sample application that can be used to understand the different parts of an ASP.NET MVC application. We take advantage of this simple application in this tutorial.

You create a new ASP.NET MVC application with the MVC template by launching Visual Studio 2008 and selecting the menu option File, New Project (see Figure 1). In the New Project dialog, select your favorite programming language under Project Types (Visual Basic or C#) and select **ASP.NET MVC Web Application** under Templates. Click the OK button.

Figure 01: New Project Dialog (Click to view full-size image)

When you create a new ASP.NET MVC application, the **Create Unit Test Project** dialog appears (see Figure 2). This dialog enables you to create a separate project in your solution for testing your ASP.NET MVC application. Select the option **No, do not create a unit test project** and click the **OK** button.

Figure 02: Create Unit Test Dialog (Click to view full-size image)

After the new ASP.NET MVC application is created. You will see several folders and files in the Solution Explorer window. In particular, you'll see three folders named Models, Views, and Controllers. As you might guess from the folder names, these folders contain the files for implementing models, views, and controllers.

If you expand the Controllers folder, you should see a file named AccountController.cs and a file named HomeController.cs. If you expand the Views folder, you should see three subfolders named Account, Home and Shared. If you expand the Home folder, you'll see two additional files named About.aspx and Index.aspx (see Figure 3). These files make up the sample application included with the default ASP.NET MVC template.

Figure 03: The Solution Explorer Window (Click to view full-size image)

You can run the sample application by selecting the menu option **Debug, Start Debugging**. Alternatively, you can press the F5 key.

When you first run an ASP.NET application, the dialog in Figure 4 appears that recommends that you enable debug mode. Click the OK button and the application will run.

Figure 04: Debugging Not Enabled dialog (Click to view full-size image)

When you run an ASP.NET MVC application, Visual Studio launches the application in your web browser. The

sample application consists of only two pages: the Index page and the About page. When the application first starts, the Index page appears (see Figure 5). You can navigate to the About page by clicking the menu link at the top right of the application.

Figure 05: The Index Page (Click to view full-size image)

Notice the URLs in the address bar of your browser. For example, when you click the About menu link, the URL in the browser address bar changes to **/Home/About**.

If you close the browser window and return to Visual Studio, you won't be able to find a file with the path Home/About. The files don't exist. How is this possible?

A URL Does Not Equal a Page

When you build a traditional ASP.NET Web Forms application or an Active Server Pages application, there is a one-to-one correspondence between a URL and a page. If you request a page named SomePage.aspx from the server, then there had better be a page on disk named SomePage.aspx. If the SomePage.aspx file does not exist, you get an ugly **404 - Page Not Found** error.

When building an ASP.NET MVC application, in contrast, there is no correspondence between the URL that you type into your browser's address bar and the files that you find in your application. In an ASP.NET MVC application, a URL corresponds to a controller action instead of a page on disk.

In a traditional ASP.NET or ASP application, browser requests are mapped to pages. In an ASP.NET MVC application, in contrast, browser requests are mapped to controller actions. An ASP.NET Web Forms application is content-centric. An ASP.NET MVC application, in contrast, is application logic centric.

Understanding ASP.NET Routing

A browser request gets mapped to a controller action through a feature of the ASP.NET framework called *ASP.NET Routing*. ASP.NET Routing is used by the ASP.NET MVC framework to *route* incoming requests to controller actions.

ASP.NET Routing uses a route table to handle incoming requests. This route table is created when your web application first starts. The route table is setup in the Global.asax file. The default MVC Global.asax file is contained in Listing 1.

Listing 1 - Global.asax

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using System.Web.Mvc;
using System.Web.Routing;

namespace MvcApplication1
{
    // Note: For instructions on enabling IIS6 or IIS7 classic mode,
    // visit https://go.microsoft.com/?LinkId=9394801

    public class MvcApplication : System.Web.HttpApplication
    {
        public static void RegisterRoutes(RouteCollection routes)
        {
            routes.IgnoreRoute("{resource}.axd/{*pathInfo}");

            routes.MapRoute(
                "Default",                                          // Route name
                "{controller}/{action}/{id}",                       // URL with parameters
                new { controller = "Home", action = "Index", id = "" }  // Parameter defaults
            );

        }

        protected void Application_Start()
        {
            RegisterRoutes(RouteTable.Routes);
        }
    }
}
```

When an ASP.NET application first starts, the Application_Start() method is called. In Listing 1, this method calls the RegisterRoutes() method and the RegisterRoutes() method creates the default route table.

The default route table consists of one route. This default route breaks all incoming requests into three segments (a URL segment is anything between forward slashes). The first segment is mapped to a controller name, the second segment is mapped to an action name, and the final segment is mapped to a parameter passed to the action named Id.

For example, consider the following URL:

/Product/Details/3

This URL is parsed into three parameters like this:

Controller = Product

Action = Details

Id = 3

The Default route defined in the Global.asax file includes default values for all three parameters. The default Controller is Home, the default Action is Index, and the default Id is an empty string. With these defaults in mind, consider how the following URL is parsed:

/Employee

This URL is parsed into three parameters like this:

Controller = Employee

Action = Index

Id =

Finally, if you open an ASP.NET MVC Application without supplying any URL (for example, `http://localhost`) then the URL is parsed like this:

Controller = Home

Action = Index

Id =

The request is routed to the Index() action on the HomeController class.

Understanding Controllers

A controller is responsible for controlling the way that a user interacts with an MVC application. A controller contains the flow control logic for an ASP.NET MVC application. A controller determines what response to send back to a user when a user makes a browser request.

A controller is just a class (for example, a Visual Basic or C# class). The sample ASP.NET MVC application includes a controller named HomeController.cs located in the Controllers folder. The content of the HomeController.cs file is reproduced in Listing 2.

Listing 2 - HomeController.cs

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using System.Web.Mvc;

namespace MvcApplication1.Controllers
{
    [HandleError]
    public class HomeController : Controller
    {
        public ActionResult Index()
        {
            ViewData["Title"] = "Home Page";
            ViewData["Message"] = "Welcome to ASP.NET MVC!";

            return View();
        }

        public ActionResult About()
        {
            ViewData["Title"] = "About Page";

            return View();
        }
    }
}
```

Notice that the HomeController has two methods named Index() and About(). These two methods correspond to the two actions exposed by the controller. The URL /Home/Index invokes the HomeController.Index() method and the URL /Home/About invokes the HomeController.About() method.

Any public method in a controller is exposed as a controller action. You need to be careful about this. This means that any public method contained in a controller can be invoked by anyone with access to the Internet by entering the right URL into a browser.

Understanding Views

The two controller actions exposed by the HomeController class, Index() and About(), both return a view. A view contains the HTML markup and content that is sent to the browser. A view is the equivalent of a page when working with an ASP.NET MVC application.

You must create your views in the right location. The HomeController.Index() action returns a view located at the following path:

\Views\Home\Index.aspx

The HomeController.About() action returns a view located at the following path:

\Views\Home\About.aspx

In general, if you want to return a view for a controller action, then you need to create a subfolder in the Views folder with the same name as your controller. Within the subfolder, you must create an .aspx file with the same name as the controller action.

The file in Listing 3 contains the About.aspx view.

Listing 3 - About.aspx

```
<%@ Page Language="C#" MasterPageFile="~/Views/Shared/Site.Master" Inherits="System.Web.Mvc.ViewPage" %>

<asp:Content ID="aboutContent" ContentPlaceHolderID="MainContent" runat="server">
    <h2>About</h2>
    <p>
        Put content here.
    </p>
</asp:Content>
```

If you ignore the first line in Listing 3, most of the rest of the view consists of standard HTML. You can modify the contents of the view by entering any HTML that you want here.

A view is very similar to a page in Active Server Pages or ASP.NET Web Forms. A view can contain HTML content and scripts. You can write the scripts in your favorite .NET programming language (for example, C# or Visual Basic .NET). You use scripts to display dynamic content such as database data.

Understanding Models

We have discussed controllers and we have discussed views. The last topic that we need to discuss is models. What is an MVC model?

An MVC model contains all of your application logic that is not contained in a view or a controller. The model should contain all of your application business logic, validation logic, and database access logic. For example, if you are using the Microsoft Entity Framework to access your database, then you would create your Entity Framework classes (your .edmx file) in the Models folder.

A view should contain only logic related to generating the user interface. A controller should only contain the bare minimum of logic required to return the right view or redirect the user to another action (flow control). Everything else should be contained in the model.

In general, you should strive for fat models and skinny controllers. Your controller methods should contain only a few lines of code. If a controller action gets too fat, then you should consider moving the logic out to a new class in the Models folder.

Summary

This tutorial provided you with a high level overview of the different parts of an ASP.NET MVC web application. You learned how ASP.NET Routing maps incoming browser requests to particular controller actions. You learned how controllers orchestrate how views are returned to the browser. Finally, you learned how models contain application business, validation, and database access logic.

Understanding Models, Views, and Controllers (VB)

9/16/2020 • 9 minutes to read • Edit Online

by Stephen Walther

> Confused about Models, Views, and Controllers? In this tutorial, Stephen Walther introduces you to the different parts of an ASP.NET MVC application.

This tutorial provides you with a high-level overview of ASP.NET MVC models, views, and controllers. In other words, it explains the M', V', and C' in ASP.NET MVC.

After reading this tutorial, you should understand how the different parts of an ASP.NET MVC application work together. You should also understand how the architecture of an ASP.NET MVC application differs from an ASP.NET Web Forms application or Active Server Pages application.

The Sample ASP.NET MVC Application

The default Visual Studio template for creating ASP.NET MVC Web Applications includes an extremely simple sample application that can be used to understand the different parts of an ASP.NET MVC application. We take advantage of this simple application in this tutorial.

You create a new ASP.NET MVC application with the MVC template by launching Visual Studio 2008 and selecting the menu option File, New Project (see Figure 1). In the New Project dialog, select your favorite programming language under Project Types (Visual Basic or C#) and select **ASP.NET MVC Web Application** under Templates. Click the OK button.

Figure 01: New Project Dialog (Click to view full-size image)

When you create a new ASP.NET MVC application, the **Create Unit Test Project** dialog appears (see Figure 2). This dialog enables you to create a separate project in your solution for testing your ASP.NET MVC application. Select the option **No, do not create a unit test project** and click the **OK** button.

Figure 02: Create Unit Test Dialog (Click to view full-size image)

After the new ASP.NET MVC application is created. You will see several folders and files in the Solution Explorer window. In particular, you'll see three folders named Models, Views, and Controllers. As you might guess from the folder names, these folders contain the files for implementing models, views, and controllers.

If you expand the Controllers folder, you should see a file named AccountController.vb and a file named HomeController.vb. If you expand the Views folder, you should see three subfolders named Account, Home and Shared. If you expand the Home folder, you'll see two additional files named About.aspx and Index.aspx (see Figure 3). These files make up the sample application included with the default ASP.NET MVC template.

Figure 03: The Solution Explorer Window (Click to view full-size image)

You can run the sample application by selecting the menu option **Debug, Start Debugging**. Alternatively, you can press the F5 key.

When you first run an ASP.NET application, the dialog in Figure 4 appears that recommends that you enable debug mode. Click the OK button and the application will run.

Figure 04: Debugging Not Enabled dialog (Click to view full-size image)

When you run an ASP.NET MVC application, Visual Studio launches the application in your web browser. The sample application consists of only two pages: the Index page and the About page. When the application first starts, the Index page appears (see Figure 5). You can navigate to the About page by clicking the menu link at the top right of the application.

Figure 05: The Index Page (Click to view full-size image)

Notice the URLs in the address bar of your browser. For example, when you click the About menu link, the URL in the browser address bar changes to **/Home/About**.

If you close the browser window and return to Visual Studio, you won't be able to find a file with the path Home/About. The files don't exist. How is this possible?

A URL Does Not Equal a Page

When you build a traditional ASP.NET Web Forms application or an Active Server Pages application, there is a one-to-one correspondence between a URL and a page. If you request a page named SomePage.aspx from the server, then there had better be a page on disk named SomePage.aspx. If the SomePage.aspx file does not exist, you get an ugly **404 - Page Not Found** error.

When building an ASP.NET MVC application, in contrast, there is no correspondence between the URL that you type into your browser's address bar and the files that you find in your application. In an ASP.NET MVC application, a URL corresponds to a controller action instead of a page on disk.

In a traditional ASP.NET or ASP application, browser requests are mapped to pages. In an ASP.NET MVC application, in contrast, browser requests are mapped to controller actions. An ASP.NET Web Forms application is content-centric. An ASP.NET MVC application, in contrast, is application logic centric.

Understanding ASP.NET Routing

A browser request gets mapped to a controller action through a feature of the ASP.NET framework called *ASP.NET Routing*. ASP.NET Routing is used by the ASP.NET MVC framework to *route* incoming requests to controller actions.

ASP.NET Routing uses a route table to handle incoming requests. This route table is created when your web application first starts. The route table is setup in the Global.asax file. The default MVC Global.asax file is contained in Listing 1.

Listing 1 - Global.asax

```
' Note: For instructions on enabling IIS6 or IIS7 classic mode,
' visit https://go.microsoft.com/?LinkId=9394802

Public Class MvcApplication
    Inherits System.Web.HttpApplication

    Shared Sub RegisterRoutes(ByVal routes As RouteCollection)
        routes.IgnoreRoute("{resource}.axd/{*pathInfo}")

        ' MapRoute takes the following parameters, in order:
        ' (1) Route name
        ' (2) URL with parameters
        ' (3) Parameter defaults
        routes.MapRoute( _
            "Default", _
            "{controller}/{action}/{id}", _
            New With {.controller = "Home", .action = "Index", .id = ""} _
        )

    End Sub

    Sub Application_Start()
        RegisterRoutes(RouteTable.Routes)
    End Sub
End Class
```

When an ASP.NET application first starts, the Application_Start() method is called. In Listing 1, this method calls the RegisterRoutes() method and the RegisterRoutes() method creates the default route table.

The default route table consists of one route. This default route breaks all incoming requests into three segments (a URL segment is anything between forward slashes). The first segment is mapped to a controller name, the second segment is mapped to an action name, and the final segment is mapped to a parameter passed to the action named Id.

For example, consider the following URL:

/Product/Details/3

This URL is parsed into three parameters like this:

Controller = Product

Action = Details

Id = 3

The Default route defined in the Global.asax file includes default values for all three parameters. The default Controller is Home, the default Action is Index, and the default Id is an empty string. With these defaults in mind, consider how the following URL is parsed:

/Employee

This URL is parsed into three parameters like this:

Controller = Employee

Action = Index

Id =

Finally, if you open an ASP.NET MVC Application without supplying any URL (for example, `http://localhost`) then the URL is parsed like this:

Controller = Home

Action = Index

Id =

The request is routed to the Index() action on the HomeController class.

Understanding Controllers

A controller is responsible for controlling the way that a user interacts with an MVC application. A controller contains the flow control logic for an ASP.NET MVC application. A controller determines what response to send back to a user when a user makes a browser request.

A controller is just a class (for example, a Visual Basic or C# class). The sample ASP.NET MVC application includes a controller named HomeController.vb located in the Controllers folder. The content of the HomeController.vb file is reproduced in Listing 2.

Listing 2 - HomeController.cs

```
<HandleError()> _
Public Class HomeController
    Inherits System.Web.Mvc.Controller

    Function Index()
        ViewData("Title") = "Home Page"
        ViewData("Message") = "Welcome to ASP.NET MVC!"

        Return View()
    End Function

    Function About()
        ViewData("Title") = "About Page"

        Return View()
    End Function
End Class
```

Notice that the HomeController has two methods named Index() and About(). These two methods correspond to the two actions exposed by the controller. The URL /Home/Index invokes the HomeController.Index() method and the URL /Home/About invokes the HomeController.About() method.

Any public method in a controller is exposed as a controller action. You need to be careful about this. This means that any public method contained in a controller can be invoked by anyone with access to the Internet by entering the right URL into a browser.

Understanding Views

The two controller actions exposed by the HomeController class, Index() and About(), both return a view. A view contains the HTML markup and content that is sent to the browser. A view is the equivalent of a page when

working with an ASP.NET MVC application.

You must create your views in the right location. The HomeController.Index() action returns a view located at the following path:

\Views\Home\Index.aspx

The HomeController.About() action returns a view located at the following path:

\Views\Home\About.aspx

In general, if you want to return a view for a controller action, then you need to create a subfolder in the Views folder with the same name as your controller. Within the subfolder, you must create an .aspx file with the same name as the controller action.

The file in Listing 3 contains the About.aspx view.

Listing 3 - About.aspx

```
<%@ Page Language="VB" MasterPageFile="~/Views/Shared/Site.Master" Inherits="System.Web.Mvc.ViewPage" %>

<asp:Content ID="aboutContent" ContentPlaceHolderID="MainContent" runat="server">
    <h2>About</h2>
    <p>
        Put content here.
    </p>
</asp:Content>
```

If you ignore the first line in Listing 3, most of the rest of the view consists of standard HTML. You can modify the contents of the view by entering any HTML that you want here.

A view is very similar to a page in Active Server Pages or ASP.NET Web Forms. A view can contain HTML content and scripts. You can write the scripts in your favorite .NET programming language (for example, C# or Visual Basic .NET). You use scripts to display dynamic content such as database data.

Understanding Models

We have discussed controllers and we have discussed views. The last topic that we need to discuss is models. What is an MVC model?

An MVC model contains all of your application logic that is not contained in a view or a controller. The model should contain all of your application business logic, validation logic, and database access logic. For example, if you are using the Microsoft Entity Framework to access your database, then you would create your Entity Framework classes (your .edmx file) in the Models folder.

A view should contain only logic related to generating the user interface. A controller should only contain the bare minimum of logic required to return the right view or redirect the user to another action (flow control). Everything else should be contained in the model.

In general, you should strive for fat models and skinny controllers. Your controller methods should contain only a few lines of code. If a controller action gets too fat, then you should consider moving the logic out to a new class in the Models folder.

Summary

This tutorial provided you with a high level overview of the different parts of an ASP.NET MVC web application. You learned how ASP.NET Routing maps incoming browser requests to particular controller actions. You learned how controllers orchestrate how views are returned to the browser. Finally, you learned how models contain application

business, validation, and database access logic.

Getting Started With MVC

2/20/2020 • 2 minutes to read • Edit Online

This is a beginner tutorial series that introduces ASP.NET MVC. Create a simple web application that reads and writes from a database.

- Intro to ASP.NET MVC
- Adding a Controller
- Adding a View
- Creating a Database
- Accessing your Model's Data from a Controller
- Adding a Create Method and Create View
- Adding Validation to the Model
- Adding a Column to the Model

Intro to ASP.NET MVC

by Scott Hanselman

> **NOTE**
>
> An updated version if this tutorial is available here using Visual Studio 2013. The new tutorial uses ASP.NET MVC 5, which provides many improvements over this tutorial.

This is a beginner tutorial that introduces the basics of ASP.NET MVC. You'll create a simple web application that reads and writes from a database. Visit the ASP.NET MVC learning center to find other ASP.NET MVC tutorials and samples.

Let's make our first ASP.NET MVC Web Application using Visual Web Developer 2010 Express. We'll make a little Movie list application that will let us create and list movies.

What You'll Build

Here are two screenshots of the application you'll build. You will have a simple table of movies with various columns.

And you'll have a Create Form so we can add movies to the list.

Skills You'll Learn

This tutorial will teach you the basics of building an ASP.NET MVC Web Application using Visual Studio. You'll learn:

- How to create a new ASP.NET MVC Project
- How to create a new Database with SQL Server
- How to create ASP.NET MVC Controllers and Views
- How to retrieve and display data
- How to edit data and enable data validation
- How to update the database schema

Get Started

Start by running Visual Web Developer 2010 Express (I'll call it "VWD" from now on) and select New Project from the Start Screen.

Visual Web Developer is an IDE, or Integrated Developer Environment. Just like you use Microsoft Word to write documents, you'll use an IDE to create applications. There's a toolbar along the top showing various options available to you, as well as the menu you could also have used to Select File | New project.

Creating Your First Application

You can create applications using Visual Basic or Visual C#. For now, Select Visual C# on the left, then pick "ASP.NET MVC 2 Web Application." Name your project "Movies" and click OK.

On the right-hand side is the Solution Explorer showing all the files and folders in your application. The big window in the middle is where you edit your code and spend most of your time. Visual Studio used a default template for the ASP.NET MVC project you just created, so you have a working application right now without doing anything! This is a simple "Hello World! project, and it is a good place to start for our application.

Select the "play" button to the toolbar.

It's a green arrow pointing to the right that will compile your program and start your application in a web browser.

NOTE: You can instead press F5 on your keyboard, or select Debug->Start Debugging from the "Debug" menu.

This will cause Visual Web Developer to start a development web-server and run our web application (there are no configuration or manual steps required to enable this). It will then launch a browser and configure it to browse the application's home-page. Notice below that the address bar of the browser says "localhost", and not something like example.com. That's because localhost always points to your own local computer - which in this case is running the application we just built.

Out of the box this default template gives you two pages to visit and a basic login page. Let's change how this application works and learn a little bit about ASP.NET MVC in the process. Close your browser and lets change some code.

Adding a Controller

2/20/2020 • 3 minutes to read • Edit Online

by Scott Hanselman

> **NOTE**
>
> An updated version if this tutorial is available here using Visual Studio 2013. The new tutorial uses ASP.NET MVC 5, which provides many improvements over this tutorial.

This is a beginner tutorial that introduces the basics of ASP.NET MVC. You'll create a simple web application that reads and writes from a database. Visit the ASP.NET MVC learning center to find other ASP.NET MVC tutorials and samples.

MVC stands for Model, View, Controller. MVC is a pattern for developing applications such that each part has a responsibility that is different from another.

- Model: The data of your application
- Views: The template files your application will use to dynamically generate HTML responses.
- Controllers: Classes that handle incoming URL requests to the application, retrieve model data, and then specify view templates that render a response back to the client

We'll be covering all these concepts in this tutorial and show you how to use them to build an application.

Let's create a new controller by right-clicking the controllers folder in the solution Explorer and selecting Add Controller.

Name your new controller "HelloWorldController" and click Add.

Notice in the Solution Explorer on the right that a new file has been created for you called HelloWorldController.cs and that file is now opened in the **IDE**.

Create two new methods that look like this inside of your new public class HelloWorldController. We'll return a string of HTML directly from our controller as an example.

```
using System.Web.Mvc;

namespace Movies.Controllers
{
    public class HelloWorldController : Controller
    {
        public string Index()
        {
            return "This is my default action...";
        }

        public string Welcome()
        {
            return "This is the Welcome action method...";
        }
    }
}
```

Your Controller is named HelloWorldController and your new Method is called Index. Run your application again, just as before (click the play button or press F5 to do this). Once your browser has started up, change the path in the address bar to `http://localhost:xx/HelloWorld` where xx is whatever number your computer has chosen. Now your browser should look like the screenshot below. In our method above we returned a string passed into a method called "Content." We told the system just returns some HTML, and it did!

ASP.NET MVC invokes different Controller classes (and different Action methods within them) depending on the incoming URL. The default mapping logic used by ASP.NET MVC uses a format like this to control what code is run:

/[Controller]/[ActionName]/[Parameters]

The first part of the URL determines the Controller class to execute. So /HelloWorld maps to the HelloWorldController class. The second part of the URL determines the Action method on the class to execute. So /HelloWorld/Index would cause the Index() method of the HelloWorldController class to execute. Notice that we only had to visit /HelloWorld above and the method Index was implied. This is because a method named "Index" is the default method that will be called on a controller if one is not explicitly specified.

Now, let's visit `http://localhost:xx/HelloWorld/Welcome.` Now our Welcome Method has executed and returned its HTML string.

Again, /[Controller]/[ActionName]/[Parameters] so Controller is HelloWorld and Welcome is the Method in this case. We haven't done Parameters yet.

Let's modify our sample slightly so that we can pass some information in from the URL to our controller, for example like this: /HelloWorld/Welcome?name=Scott&numtimes=4. Change your Welcome method to include

two parameters and update it like below. Note that we've used the C# optional parameter feature to indicate that the parameter numTimes should default to 1 if it's not passed in.

```
public string Welcome(string name, int numTimes = 1)
{
   string message = "Hello " + name + ", NumTimes is: " + numTimes;
   return "" + Server.HtmlEncode(message) + "";
}
```

Run your application and visit `http://localhost:xx/HelloWorld/Welcome?name=Scott&numtimes=4` changing the value of name and numtimes as you like. The system automatically mapped the named parameters from your query string in the address bar to parameters in your method.

In both these examples the controller has been doing all the work, and has been returning HTML directly. Ordinarily we don't want our Controllers returning HTML directly - since that ends up being very cumbersome to code. Instead we'll typically use a separate View template file to help generate the HTML response. Let's look at how we can do this. Close your browser and return to the IDE.

Adding a View

2/20/2020 • 6 minutes to read • Edit Online

by Scott Hanselman

> This is a beginner tutorial that introduces the basics of ASP.NET MVC. You'll create a simple web application that reads and writes from a database. Visit the ASP.NET MVC learning center to find other ASP.NET MVC tutorials and samples.

In this section we are going to look at how we can have our HelloWorldController class use a View template file to cleanly encapsulate generating HTML responses back to a client.

Let's start by using a View template with our Index method. Our method is called Index and it's in the HelloWorldController. Currently our Index() method returns a string with a message that is hardcoded within the Controller class.

```
public string Index()
{
    return "<html><body>This is my default action...</body></html>";
}
```

Let's now change the Index method to instead look like this:

```
public ActionResult Index()
{
   return View();
}
```

Let's now add a View template to our project that we can use for our Index() method. To do this, right-click with your mouse somewhere in the middle of the Index method and click Add View...

This will bring up the "Add View" dialog which provides us some options for how we want to create a view template that can be used by our Index method. For now, don't change anything, and just click the Add button.

After you click Add, a new folder and a new file will appear in the Solution Folder, as seen here. I now have a HelloWorld folder under Views, and an Index.aspx file inside that folder.

The new Index file is also already opened and ready for editing. Add some text under the first <h2>Index</h2> like "Hello World."

```
<h2>Index</h2>
Hello world!
```

Run your application and visit `http://localhost:xx/HelloWorld` again in your browser. The Index method in our controller in this example didn't do any work, but did call "return View()" which indicated that we wanted to use a view template file to render a response back to the client. Because we did not explicitly specify the name of the view template file to use, ASP.NET MVC defaulted to using the Index.aspx view file within the \Views\HelloWorld folder. Now we see the string we hard-coded in our View.

Looks pretty good. However, notice that the Browser's title says "Index" and the big title on the page says "My MVC Application." Let's change those.

Changing Views and Master Pages

First, let's change the text "My MVC Application." That text is shared and appears on every page. It actually appears in only one place in our code, even though it's on every page in our app. Go to the /Views/Shared folder in the Solution Explorer and open the Site.Master file. This file is called a Master Page and it's the shared "shell" that all our other pages use.

Notice some text that says ContentPlaceholder "MainContent" in this file.

```
<asp:ContentPlaceHolder ID="MainContent" runat="server" />
```

That placeholder is where all the pages you create will show up, "wrapped" in the master page. Try changing the title, then run your app and visit multiple pages. You'll notice that your one change appears on multiple pages.

```
<div id="title">
    <h1>My MVC Movie Application</h1>
</div>
```

Now every page will have the Primary Heading - that's H1 - of "My MVC Movie Application." That handles the white text at the top there that's shared across all the pages.

Here is the Site.Master in its entirety with our changed title:

```
<%@ Master Language="C#" Inherits="System.Web.Mvc.ViewMasterPage" %>

<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Strict//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-strict.dtd">
<html xmlns="http://www.w3.org/1999/xhtml">
<head runat="server">
    <title><asp:ContentPlaceHolder ID="TitleContent" runat="server" /></title>
    <link href="../../Content/Site.css" rel="stylesheet" type="text/css" />
</head>

<body>
    <div class="page">

        <div id="header">
            <div id="title">
                <h1>My MVC Movie Application</h1>
            </div>

            <div id="logindisplay">
                <% Html.RenderPartial("LogOnUserControl"); %>
            </div>

            <div id="menucontainer">

                <ul id="menu">
                    <li><%: Html.ActionLink("Home", "Index", "Home")%></li>
                    <li><%: Html.ActionLink("About", "About", "Home")%></li>
                </ul>

            </div>
        </div>

        <div id="main">
            <asp:ContentPlaceHolder ID="MainContent" runat="server" />

            <div id="footer">
            </div>
        </div>
    </div>
</body>
</html>
```

Now, let's change the title of the Index page.

Open /HelloWorld/Index.aspx. There's two places to change. First, the Title that appears in the title of the browser, then the secondary header - that's H2 - as well. I'll make them each slightly different so you can see which bit of code changes which part of the app.

```
<asp:Content ID="Content1" ContentPlaceHolderID="TitleContent" runat="server">
    Movie List
</asp:Content>

<asp:Content ID="Content2" ContentPlaceHolderID="MainContent" runat="server">

    <h2>My Movie List</h2>
    Hello World!

</asp:Content>
```

Run your app and visit /Movies. Notice that the browser title, the primary heading and the secondary headings have changed. It's easy to make big changes in your app with small changes to your view.

Our little bit of "data" (in this case the "Hello World!" message) was hard coded though. We've got V (Views) and we've got C (Controllers), but no M (Model) yet. We'll shortly walk through how create a database and retrieve model data from it.

Passing a ViewModel

Before we go to a database and talk about Models, though, let's first talk about "ViewModels." These are objects that represent what a View template requires to render an HTML response back to a client. They are typically created and passed by a Controller class to a View template, and should only contain the data that the View template requires - and no more.

Previously with our HelloWorld sample, our Welcome() action method took a name and a numTimes parameter and output it to the browser. Rather than have the Controller continue to render this response directly,let's instead make a small class to hold that data and then pass it over to a View template to render back the HTML response using it. This way the Controller is concerned with one thing and the View template another – enabling us to maintain clean "separation of concerns" within our application.

Return to the HelloWorldController.cs file and add a new "WelcomeViewModel" class and change the Welcome method inside your controller. Here is the complete HelloWorldController.cs with the new class in the same file.

```
using System.Web.Mvc;

namespace Movies.Controllers
{
    public class HelloWorldController : Controller
    {
        public ActionResult Index()
        {
            return View();
        }

        public ActionResult Welcome(string name, int numTimes = 1)
        {
            var viewModel = new WelcomeViewModel
            {
                Message = "Hello " + name,
                NumTimes = numTimes
            };

            return View(viewModel);
        }

        public class WelcomeViewModel
        {
            public string Message { get; set; }
            public int NumTimes { get; set; }
        }
    }
}
```

Even though it's on multiple lines, our Welcome method is really only two code statements. The first statement packages up our two parameters into a ViewModel object, and the second passes the resulting object onto the View.

Now we need a Welcome View template! Right click in the Welcome method and select Add View. This time, we'll check "Create a strongly-typed view" and select our WelcomeViewModel class from the drop down list. This new view will only know about WelcomeViewModels and no other types of objects.

> *NOTE: You'll need to have compiled once after adding your WelcomeViewModel for to show up in the drop down list.*

Here's what your Add View dialog should look like. Click the Add button.

Add this code under the <h2> in your new Welcome.aspx. We'll make a loop and say Hello as many times as the user says we should!

```
<% for(int i=0;i<Model.NumTimes;i++) { %>
        <%h3><%: Model.Message %></h3>
<% } %>
```

Also, notice while you're typing that because we told this View about the WelcomeViewModel (they are married, remember?) that we get helpful Intellisense each time we reference our Model object as seen in the screenshot below:

Run your application and visit `http://localhost:xx/HelloWorld/Welcome?name=Scott&numtimes=4` again. Now we're taking data from the URL, it's passed into our Controller automatically, our Controller packages up the data into a ViewModel and passes that object onto our View. The View than displays the data as HTML to the user.

Well, that was a kind of an "M" for Model, but not the database kind. Let's take what we've learned and create a database of Movies.

PREVIOUS NEXT

Creating a Database

2/20/2020 • 2 minutes to read • Edit Online

by Scott Hanselman

This is a beginner tutorial that introduces the basics of ASP.NET MVC. You'll create a simple web application that reads and writes from a database. Visit the ASP.NET MVC learning center to find other ASP.NET MVC tutorials and samples.

In this section we are going to create a new SQL Express database that we'll use to store and retrieve our movie data. From within the Visual Web Developer IDE, select View | Server Explorer. Right click on Data Connections and click Add Connection...

In the Choose Data Source dialog, select Microsoft SQL Server and select Continue.

In the Add Connection dialog, enter ".\SQLEXPRESS" for your Server Name, and enter "Movies" as the name for your new database.

Click OK and you'll be asked if you want to create that database. Select yes.

Now you've got an empty database in Server Explorer.

Right click on Tables and click Add Table. The Table Designer will appear. Add columns for Id, Title, ReleaseDate, Genre, and Price. Right click on the ID column and click set Primary Key. Here's what my design areas looks like.

Also, select the Id column and under Column Properties below change "Identity Specification" to "Yes."

When you've got it done, click the Save icon in the toolbar or select File | Save from the menu, and name your table "**Movie**" (singular). We've got a database and a table!

Go back to Server Explorer and right click the Movie table, then select "Show Table Data." Enter a few movies so our database has some data.

Movie: Query(hexpo...sqlexpress.Movies) | Movies.edmx | Web.config* | MoviesController.cs

Id	Title	ReleaseDate	Genre	Price
1	Ghostbusters	1/1/1984	Comedy	10
2	Ghostbusters 2	1/1/1986	Comedy	9
3	Ghostbusters 3	1/1/2012	Comedy	98
NULL	NULL	NULL	NULL	NULL

Creating a Model

Now, switch back to the Solution Explorer on the right hand side of the IDE and right-click on the Models folder and select Add | New Item.

We're going to create an Entity Model from our new database. This will add a set of classes to our project that makes it easy for us to query and manipulate the data within our database. Select the Data node on the left-hand side of the dialog, and then select the ADO.NET Entity Data Model item template. Name it Movies.edmx.

Click the "Add" button. This will then launch the "Entity Data Model Wizard".

In the new dialog that pops up, select Generate from Database. Since we've just made a database, we'll only need to tell the Entity Framework about our new database and its table. Click Next to save our database connection in our web application's configuration. Now, check the Tables and Movie checkbox and click Finish.

Now we can see our new Movie table in the Entity Framework Designer and access it from code.

On the design surface you can see a "Movie" class. This class maps to the "Movie" table in our database, and each property within it maps to a column with the table. Each instance of a "Movie" class will correspond to a row within the "Movie" table.

If you don't like the default naming and mapping conventions used by the Entity Framework, you can use the Entity Framework designer to change or customize them. For this application we'll use the defaults and just save the file as-is.

Now, let's work with some real data!

Accessing your Model's Data from a Controller

2/20/2020 • 2 minutes to read • Edit Online

by Scott Hanselman

This is a beginner tutorial that introduces the basics of ASP.NET MVC. You'll create a simple web application that reads and writes from a database. Visit the ASP.NET MVC learning center to find other ASP.NET MVC tutorials and samples.

In this section we are going to create a new MoviesController class, and write some code that retrieves our Movie data and displays it back to the browser using a View template.

Right click on the Controllers folder and make a new MoviesController.

This will create a new "MoviesController.cs" file underneath our \Controllers folder within our project. Let's update the MovieController to retrieve the list of movies from our newly populated database.

```
using System;
using System.Linq;
using System.Web.Mvc;
using Movies.Models;

namespace Movies.Controllers
{
    public class MoviesController : Controller
    {
        MoviesEntities db = new MoviesEntities();

        public ActionResult Index()
        {
            var movies = from m in db.Movies
                         where m.ReleaseDate > new DateTime(1984, 6, 1)
                         select m;

            return View(movies.ToList());

        }
    }
}
```

We are performing a LINQ query so that we only retrieve movies released after the summer of 1984. We'll need a View template to render this list of movies back, so right-click in the method and select Add View to create it.

Within the Add View dialog we'll indicate that we are passing a List<Movies.Models.Movie> to our View template.

Unlike the previous times we used the Add View dialog and chose to create an "Empty" template, this time we'll indicate that we want Visual Studio to automatically "scaffold" a view template for us with some default content. We'll do this by selecting the "List" item within the "View content dropdown menu.

Remember, when you have a created a new class you'll need to compile your application for it to show up in the Add View Dialog.

Click add and the system will automatically generate the code for a View for us that displays our list of movies. This is a good time to change the <h2> heading to something like "My Movie List" like we did earlier with the Hello World view.

Run your application and visit /Movies in the address bar. Now we've retrieved data from the database using a basic query inside the Controller and returned the data to a View that knows about Movies. That View then spins through the list of Movies and creates a table of data for us.

We won't be implementing Edit, Details and Delete functionality with this application - so we don't need the default links that the scaffold template created for us. Open up the /Movies/Index.aspx file and remove them.

Here is the source code for what our updated View template should look like once we make these changes:

```
<%@ Page Title="" Language="C#" MasterPageFile="~/Views/Shared/Site.Master"
Inherits="System.Web.Mvc.ViewPage<IEnumerable<Movies.Models.Movie>>" %>

<asp:Content ID="Content1" ContentPlaceHolderID="TitleContent" runat="server">
    Movie List
</asp:Content>
<asp:Content ID="Content2" ContentPlaceHolderID="MainContent" runat="server">
    <h2>My Movie List</h2>
    <table>
        <tr>
            <th>Title</th>
            <th>ReleaseDate</th>
            <th>Genre</th>
            <th>Rating</th>
            <th>Price</th>
        </tr>
        <% foreach (var item in Model)
           { %>
        <tr>
            <td><%: item.Title %></td>
            <td><%: String.Format("{0:g}", item.ReleaseDate) %></td>
            <td><%: item.Genre %></td>
            <td><%: item.Rating %></td>
            <td><%: String.Format("{0:F}", item.Price) %></td>
        </tr>
        <% } %>
    </table>
    <p>
        <%: Html.ActionLink("Create New", "Create") %>
    </p>
</asp:Content>
```

It's creating links that we won't need, so we'll delete them for this example. We will keep our Create New link though, as that's next! Here's what our app looks like with that column removed.

We now have a simple listing of our movie data. However, if we click the "Create New" link, we'll get an error as it's not hooked up! Let's implement a Create Action method and enable a user to enter new movies in our database.

PREVIOUS NEXT

Adding a Create Method and Create View

2/20/2020 • 4 minutes to read • Edit Online

by Scott Hanselman

> This is a beginner tutorial that introduces the basics of ASP.NET MVC. You'll create a simple web application that reads and writes from a database. Visit the ASP.NET MVC learning center to find other ASP.NET MVC tutorials and samples.

In this section we are going to implement the support necessary to enable users to create new movies in our database. We'll do this by implementing the /Movies/Create URL action.

Implementing the /Movies/Create URL is a two step process. When a user first visits the /Movies/Create URL we want to show them an HTML form that they can fill out to enter a new movie. Then, when the user submits the form and posts the data back to the server, we want to retrieve the posted contents and save it into our database.

We'll implement these two steps within two Create() methods within our MoviesController class. One method will show the <form> that the user should fill out to create a new movie. The second method will handle processing the posted data when the user submits the <form> back to the server, and save a new Movie within our database.

Below is the code we'll add to our MoviesController class to implement this:

```
public ActionResult Create()
{
    return View();
}

[HttpPost]
public ActionResult Create(Movie newMovie)
{

    if (ModelState.IsValid)
    {
        db.AddToMovies(newMovie);
        db.SaveChanges();

        return RedirectToAction("Index");
    }
    else
    {
        return View(newMovie);
    }
}
```

The above code contains all of the code that we'll need within our Controller.

Let's now implement the Create View template that we'll use to display a form to the user. We'll right click in the first Create method and select "Add View" to create the view template for our Movie form.

We'll select that we are going to pass the view template a "Movie" as its view data class, and indicate that we want to "scaffold" a "Create" template.

After you click the Add button, \Movies\Create.aspx View template will be created for you. Because we selected "Create" from the "view content" dropdown, the Add View dialog automatically "scaffolded" some default content for us. The scaffolding created an HTML <form>, a place for validation error messages to go, and since scaffolding knows about Movies, it created Label and Fields for each property of our class.

```
<% using (Html.BeginForm()) {%>
    <%: Html.ValidationSummary(true) %>

    <fieldset>
        <legend>Fields</legend>

        <div class="editor-label">
            <%: Html.LabelFor(model => model.Id) %>
        </div>
        <div class="editor-field">
            <%: Html.TextBoxFor(model => model.Id) %>
            <%: Html.ValidationMessageFor(model => model.Id) %>
        </div>

        <div class="editor-label">
            <%: Html.LabelFor(model => model.Title) %>
        </div>
        <div class="editor-field">
            <%: Html.TextBoxFor(model => model.Title) %>
            <%: Html.ValidationMessageFor(model => model.Title) %>
        </div>

        <div class="editor-label">
            <%: Html.LabelFor(model => model.ReleaseDate) %>
        </div>
        <div class="editor-field">
            <%: Html.TextBoxFor(model => model.ReleaseDate) %>
            <%: Html.ValidationMessageFor(model => model.ReleaseDate) %>
        </div>

        <div class="editor-label">
            <%: Html.LabelFor(model => model.Genre) %>
        </div>
        <div class="editor-field">
            <%: Html.TextBoxFor(model => model.Genre) %>
            <%: Html.ValidationMessageFor(model => model.Genre) %>
        </div>

        <div class="editor-label">
            <%: Html.LabelFor(model => model.Price) %>
        </div>
        <div class="editor-field">
            <%: Html.TextBoxFor(model => model.Price) %>
            <%: Html.ValidationMessageFor(model => model.Price) %>
        </div>

        <p>
            <input type="submit" value="Create" />
        </p>
    </fieldset>

<% } %>
```

Since our database automatically gives a Movie an ID, let's remove those fields that reference model.Id from our Create View. Remove the 7 lines after <legend>Fields</legend> as they show the ID field that we don't want.

Let's now create a new movie and add it to the database. We'll do this by running the application again and visit the "/Movies" URL and click the "Create" link to add a new Movie.

When we click the Create button, we'll be posting back (via HTTP POST) the data on this form to the /Movies/Create method that we just created. Just like when the system automatically took the "numTimes" and "name " parameter out of the URL and mapped them to parameters on a method earlier, the system will automatically take the Form Fields from a POST and map them to an object. In this case, values from fields in HTML like "ReleaseDate" and "Title" will automatically be put into the correct properties of a new instance of a Movie.

Let's look at the second Create method from our MoviesController again. Notice how it takes a "Movie" object as an argument:

```
[HttpPost]
public ActionResult Create(Movie newMovie)
{
    if (ModelState.IsValid)
    {
        db.AddToMovies(newMovie);
        db.SaveChanges();

        return RedirectToAction("Index");
    }
    else
    {
        return View(newMovie);
    }
}
```

This Movie object was then passed to the [HttpPost] version of our Create action method, and we saved it in the

database and then redirected the user back to the Index() action method which will show the saved result in the movie list:

We aren't checking if our movies are correct, though, and the database won't allow us to save a movie with no Title. It'd be nice if we could tell the user that before the database threw an error. We'll do this next by adding validation support to our application.

Adding Validation to the Model

2/20/2020 • 2 minutes to read • Edit Online

by Scott Hanselman

This is a beginner tutorial that introduces the basics of ASP.NET MVC. You'll create a simple web application that reads and writes from a database. Visit the ASP.NET MVC learning center to find other ASP.NET MVC tutorials and samples.

In this section we are going to implement the support necessary to enable input validation within our application. We'll ensure that our database content is always correct, and provide helpful error messages to end users when they try and enter Movie data which is not valid. We'll begin by adding a little validation logic to the Movie class.

Right click on the Model folder and select Add Class. Name your class Movie.

When we created the Movie Entity Model earlier, the IDE created a Movie class. In fact, part of the Movie class can be in one file and part in another. This is called a Partial Class. We're going to extend the Movie class from another file.

We'll create a partial movie class that points to a "buddy class" with some attributes that will give validation hints to the system. We'll mark the Title and Price as Required, and also insist that the Price be within a certain range. Right click the Models folder and select Add Class. Name your class Movie and Click the OK button. Here's what our partial Movie class looks like.

```
using System.ComponentModel.DataAnnotations;

namespace Movies.Models
{
    [MetadataType(typeof(MovieMetadata))]
    public partial class Movie
    {
        class MovieMetadata
        {
            [Required(ErrorMessage="Titles are required")]
            public string Title { get; set; }

            [Range(5,100,ErrorMessage ="Movies cost between $5 and $100.")]
            public decimal Price { get; set; }
        }
    }
}
```

Re-Run your application and try to enter a movie with a price over 100. You'll get an error after you've submitted the form. The error is caught on the server side and occurs after the Form is POSTed. Notice how ASP.NET MVC's built-in HTML helpers were smart enough to display the error message and maintain the values for us within the textbox elements:

This works great, but it'd be nice if we could tell the user on the client-side, immediately, before the server gets involved.

Let's enable some client-side validation with JavaScript.

Adding Client-Side Validation

Since our Movie class already has some validation attributes, we'll just need to add a few JavaScript files to our Create.aspx View template and add a line of code to enable client-side validation to take place.

From within VWD go our Views/Movie folder and open up Create.aspx.

Open up the Scripts folder in the Solution Explorer and drag the following three scripts to within the <head> tag.

- MicrosoftAjax.js
- MicrosoftMvcValidation.js

You want these script files to appear in this order.

```
<script src="/Scripts/MicrosoftAjax.js" type="text/javascript"></script>
<script src="/Scripts/MicrosoftMvcValidation.js" type="text/javascript"></script>
```

Also, add this single line above the Html.BeginForm:

```
<% Html.EnableClientValidation(); %>
```

Here's the code shown within the IDE.

Run your application and visit /Movies/Create again, and click Create without entering any data. The error messages appear immediately without the page flash that we associate with sending data all the way back to the server. This is because ASP.NET MVC is now validating the input on both the client (using JavaScript) and on the server.

This is looking good! Let's now add one additional column to the database.

PREVIOUS NEXT

Adding a Column to the Model

2/20/2020 • 4 minutes to read • Edit Online

by Scott Hanselman

> This is a beginner tutorial that introduces the basics of ASP.NET MVC. You'll create a simple web application that reads and writes from a database. Visit the ASP.NET MVC learning center to find other ASP.NET MVC tutorials and samples.

In this section we are going to walk through how we can make changes to the schema of our database, and handle the changes within our application.

Let's add a "Rating" Column to the Movie table. Go back to the IDE and click the Database Explorer. Right click the Movie table and select Open Table Definition.

Add a "Rating" column as seen below. Since we don't have any Ratings now, the column can allow nulls. Click Save.

Next, return to the Solution Explorer and open up the Movies.edmx file (which is in the \Models folder). Right click on the design surface (the white area) and select Update Model from Database.

This will launch the "Update Wizard". Click the Refresh tab within it and click Finish. Our Movie model class will then be updated with the new column.

After clicking Finish, you can see the new Rating Column has been added to the Movie Entity in our model.

We've added a column in the database model, but the Views don't know about it.

Update Views with Model Changes

There are a few ways we could update our view templates to reflect the new Rating column. Since we created these Views by generating them via the Add View dialog, we could delete them and recreate them again. However, typically people will have already made modifications to their View templates from the initial scaffolded generation and will want to add or delete fields manually, just as we did with the ID field for Create.

Open up the \Views\Movies\Index.aspx template and add a <th>Rating</th> to the head of the Movie table. I added mine after Genre. Then, in the same column position but lower down, add a line to output our new Rating.

```
<td>
  <%: item.Rating %>
</td>
```

Our final Index.aspx template will look like this:

```
<%@ Page Title="" Language="C#" MasterPageFile="~/Views/Shared/Site.Master"
Inherits="System.Web.Mvc.ViewPage<IEnumerable<Movies.Models.Movie>>" %>

<asp:Content ID="Content1" ContentPlaceHolderID="TitleContent" runat="server">
    Movie List
</asp:Content>
<asp:Content ID="Content2" ContentPlaceHolderID="MainContent" runat="server">
    <h2>My Movie List</h2>
    <table>
        <tr>
            <th>Id</th>
            <th>Title</th>
            <th>ReleaseDate</th>
            <th>Genre</th>
            <th>Rating</th>
            <th>Price</th>
        </tr>
        <% foreach (var item in Model)
           { %>
        <tr>
            <td><%: item.Id %></td>
            <td><%: item.Title %></td>
            <td><%: String.Format("{0:g}", item.ReleaseDate) %></td>
            <td><%: item.Genre %></td>
            <td><%: item.Rating %></td>
            <td><%: String.Format("{0:F}", item.Price) %></td>
        </tr>
        <% } %>
    </table>
    <p>
        <%: Html.ActionLink("Create New", "Create") %>
    </p>
</asp:Content>
```

Let's then open up the \Views\Movies\Create.aspx template and add a Label and Textbox for our new Rating property:

```
<div class="editor-label">
    <%: Html.LabelFor(model => model.Rating) %>
</div>
<div class="editor-field">
    <%: Html.TextBoxFor(model => model.Rating)%>
    <%: Html.ValidationMessageFor(model => model.Rating)%>
</div>
```

Our final Create.aspx template will look like this, and let's change our browser's title and secondary <h2> title to something like "Create a Movie" while we're in here!

```
<%@ Page Title="" Language="C#" MasterPageFile="~/Views/Shared/Site.Master"
Inherits="System.Web.Mvc.ViewPage<Movies.Models.Movie>" %>

<asp:Content ID="Content1" ContentPlaceHolderID="TitleContent" runat="server">
    Create a Movie
</asp:Content>

<asp:Content ID="Content2" ContentPlaceHolderID="MainContent" runat="server">
```

```
    <script src="../../Scripts/MicrosoftAjax.js" type="text/javascript"></script>
    <script src="../../Scripts/MicrosoftMvcValidation.js" type="text/javascript"></script>
    <h2>Create a Movie</h2>
    <% Html.EnableClientValidation(); %>
    <% using (Html.BeginForm()) {%>
        <%: Html.ValidationSummary(true) %>

        <fieldset>
            <legend>Fields</legend>

            <div class="editor-label">
                <%: Html.LabelFor(model => model.Title) %>
            </div>
            <div class="editor-field">
                <%: Html.TextBoxFor(model => model.Title) %>
                <%: Html.ValidationMessageFor(model => model.Title) %>
            </div>

            <div class="editor-label">
                <%: Html.LabelFor(model => model.ReleaseDate) %>
            </div>
            <div class="editor-field">
                <%: Html.TextBoxFor(model => model.ReleaseDate) %>
                <%: Html.ValidationMessageFor(model => model.ReleaseDate) %>
            </div>

            <div class="editor-label">
                <%: Html.LabelFor(model => model.Genre) %>
            </div>
            <div class="editor-field">
                <%: Html.TextBoxFor(model => model.Genre) %>
                <%: Html.ValidationMessageFor(model => model.Genre) %>
            </div>

            <div class="editor-label">
                <%: Html.LabelFor(model => model.Rating) %>
            </div>
            <div class="editor-field">
                <%: Html.TextBoxFor(model => model.Rating)%>
                <%: Html.ValidationMessageFor(model => model.Rating)%>
            </div>

            <div class="editor-label">
                <%: Html.LabelFor(model => model.Price) %>
            </div>
            <div class="editor-field">
                <%: Html.TextBoxFor(model => model.Price) %>
                <%: Html.ValidationMessageFor(model => model.Price) %>
            </div>

            <p>
                <input type="submit" value="Create" />
            </p>
        </fieldset>

    <% } %>

    <div>
        <%: Html.ActionLink("Back to List", "Index") %>
    </div>

</asp:Content>
```

Run your app and now you've got a new field in the database that's been added to the Create page. Add a new Movie - this time with a Rating - and click Create.

After you click Create, you're sent to the Index page where you new Movie is listed with the new Rating Column in the database

This basic tutorial got you started making Controllers, associating them with Views and passing around hard-

coded data. Then we created and designed a Database and put some data it in. We retrieved the data from the database and displayed it in an HTML table. Then we added a Create form that let the user add data to the database themselves from within the Web Application. We added validation, then made the validation use JavaScript on the client-side. Finally, we changed the database to include a new column of data, then updated our two pages to create and display this new data.

I now encourage you to move on to our intermediate-level tutorial "MVC Music Store" as well as the many videos and resources at https://asp.net/mvc to learn even more about ASP.NET MVC!

Enjoy!

Models (Data)

2/20/2020 • 2 minutes to read • Edit Online

In this tutorial series, you learn how to use ASP.NET MVC with the Microsoft Entity Framework. Over the course of this tutorial, you build a web application that illustrates how to select, insert, update, and delete database data by using the Entity Framework.

- Creating Model Classes with the Entity Framework (C#)
- Creating Model Classes with LINQ to SQL (C#)
- Displaying a Table of Database Data (C#)
- Performing Simple Validation (C#)
- Validating with the IDataErrorInfo Interface (C#)
- Validating with a Service Layer (C#)
- Validation with the Data Annotation Validators (C#)
- Creating Model Classes with the Entity Framework (VB)
- Creating Model Classes with LINQ to SQL (VB)
- Displaying a Table of Database Data (VB)
- Performing Simple Validation (VB)
- Validating with the IDataErrorInfo Interface (VB)
- Validating with a Service Layer (VB)
- Validation with the Data Annotation Validators (VB)

Creating Model Classes with the Entity Framework (C#)

4/10/2020 • 12 minutes to read • Edit Online

by Microsoft

> In this tutorial, you learn how to use ASP.NET MVC with the Microsoft Entity Framework. You learn how to use the Entity Wizard to create an ADO.NET Entity Data Model. Over the course of this tutorial, we build a web application that illustrates how to select, insert, update, and delete database data by using the Entity Framework.

The goal of this tutorial is to explain how you can create data access classes using the Microsoft Entity Framework when building an ASP.NET MVC application. This tutorial assumes no previous knowledge of the Microsoft Entity Framework. By the end of this tutorial, you'll understand how to use the Entity Framework to select, insert, update, and delete database records.

The Microsoft Entity Framework is an Object Relational Mapping (O/RM) tool that enables you to generate a data access layer from a database automatically. The Entity Framework enables you to avoid the tedious work of building your data access classes by hand.

In order to illustrate how you can use the Microsoft Entity Framework with ASP.NET MVC, we'll build a simple sample application. We'll create a Movie Database application that enables you to display and edit movie database records.

This tutorial assumes that you have Visual Studio 2008 or Visual Web Developer 2008 with Service Pack 1. You need Service Pack 1 in order to use the Entity Framework. You can download Visual Studio 2008 Service Pack 1 or Visual Web Developer with Service Pack 1 from the following address:

> https://www.asp.net/downloads/

NOTE

There is no essential connection between ASP.NET MVC and the Microsoft Entity Framework. There are several alternatives to the Entity Framework that you can use with ASP.NET MVC. For example, you can build your MVC Model classes using other O/RM tools such as Microsoft LINQ to SQL, NHibernate, or SubSonic.

Creating the Movie Sample Database

The Movie Database application uses a database table named Movies that contains the following columns:

COLUMN NAME	DATA TYPE	ALLOW NULLS?	IS PRIMARY KEY?
Id	int	False	True
Title	nvarchar(100)	False	False
Director	nvarchar(100)	False	False

You can add this table to an ASP.NET MVC project by following these steps:

1. Right-click the App_Data folder in the Solution Explorer window and select the menu option **Add, New Item.**
2. From the **Add New Item** dialog box, select **SQL Server Database**, give the database the name MoviesDB.mdf, and click the **Add** button.
3. Double-click the MoviesDB.mdf file to open the Server Explorer/Database Explorer window.
4. Expand the MoviesDB.mdf database connection, right-click the Tables folder, and select the menu option **Add New Table**.
5. In the Table Designer, add the Id, Title, and Director columns.
6. Click the **Save** button (it has the icon of the floppy) to save the new table with the name Movies.

After you create the Movies database table, you should add some sample data to the table. Right-click the Movies table and select the menu option **Show Table Data**. You can enter fake movie data into the grid that appears.

Creating the ADO.NET Entity Data Model

In order to use the Entity Framework, you need to create an Entity Data Model. You can take advantage of the Visual Studio *Entity Data Model Wizard* to generate an Entity Data Model from a database automatically.

Follow these steps:

1. Right-click the Models folder in the Solution Explorer window and select the menu option **Add, New Item**.
2. In the **Add New Item** dialog, select the Data category (see Figure 1).
3. Select the **ADO.NET Entity Data Model** template, give the Entity Data Model the name MoviesDBModel.edmx, and click the **Add** button. Clicking the **Add** button launches the Data Model Wizard.
4. In the **Choose Model Contents** step, choose the **Generate from a database** option and click the **Next** button (see Figure 2).
5. In the **Choose Your Data Connection** step, select the MoviesDB.mdf database connection, enter the entities connection settings name MoviesDBEntities, and click the **Next** button (see Figure 3).
6. In the **Choose Your Database Objects** step, select the Movie database table and click the **Finish** button (see Figure 4).

After you complete these steps, the ADO.NET Entity Data Model Designer (Entity Designer) opens.

Figure 1 – Creating a new Entity Data Model

Figure 2 – Choose Model Contents Step

Figure 3 – Choose Your Data Connection

Figure 4 – Choose Your Database Objects

Modifying the ADO.NET Entity Data Model

After you create an Entity Data Model, you can modify the model by taking advantage of the Entity Designer (see Figure 5). You can open the Entity Designer at any time by double-clicking the MoviesDBModel.edmx file contained in the Models folder within the Solution Explorer window.

Figure 5 – The ADO.NET Entity Data Model Designer

For example, you can use the Entity Designer to change the names of the classes that the Entity Model Data Wizard generates. The Wizard created a new data access class named Movies. In other words, the Wizard gave the class the very same name as the database table. Because we will use this class to represent a particular Movie instance, we should rename the class from Movies to Movie.

If you want to rename an entity class, you can double-click on the class name in the Entity Designer and enter a new name (see Figure 6). Alternatively, you can change the name of an entity in the Properties window after selecting an entity in the Entity Designer.

Figure 6 – Changing an entity name

Remember to save your Entity Data Model after making a modification by clicking the Save button (the icon of the floppy disk). Behind the scenes, the Entity Designer generates a set of C# classes. You can view these classes by opening the MoviesDBModel.Designer.cs file from the Solution Explorer window.

Don't modify the code in the Designer.cs file since your changes will be overwritten the next time you use the Entity Designer. If you want to extend the functionality of the entity classes defined in the Designer.cs file then you can create *partial classes* in separate files.

Selecting Database Records with the Entity Framework

Let's start building our Movie Database application by creating a page that displays a list of movie records. The

Home controller in Listing 1 exposes an action named Index(). The Index() action returns all of the movie records from the Movie database table by taking advantage of the Entity Framework.

Listing 1 – Controllers\HomeController.cs

```
using System.Linq;
using System.Web.Mvc;
using MovieEntityApp.Models;

namespace MovieEntityApp.Controllers
{
    [HandleError]
    public class HomeController : Controller
    {
        MoviesDBEntities _db;

        public HomeController()
        {
            _db = new MoviesDBEntities();
        }

        public ActionResult Index()
        {
            ViewData.Model = _db.MovieSet.ToList();
            return View();
        }

    }
}
```

Notice that the controller in Listing 1 includes a constructor. The constructor initializes a class-level field named _db. The _db field represents the database entities generated by the Microsoft Entity Framework. The _db field is an instance of the MoviesDBEntities class that was generated by the Entity Designer.

In order to use theMoviesDBEntities class in the Home controller, you must import the MovieEntityApp.Models namespace (*MVCProjectName*.Models).

The _db field is used within the Index() action to retrieve the records from the Movies database table. The expression _db.MovieSet represents all of the records from the Movies database table. The ToList() method is used to convert the set of movies into a generic collection of Movie objects (List<Movie>).

The movie records are retrieved with the help of LINQ to Entities. The Index() action in Listing 1 uses LINQ *method syntax* to retrieve the set of database records. If you prefer, you can use LINQ *query syntax* instead. The following two statements do the very same thing:

```
ViewData.Model = _db.MovieSet.ToList();
ViewData.Model = (from m in _db.MovieSet select m).ToList();
```

Use whichever LINQ syntax – method syntax or query syntax – that you find most intuitive. There is no difference in performance between the two approaches – the only difference is style.

The view in Listing 2 is used to display the movie records.

Listing 2 – Views\Home\Index.aspx

```
<%@ Page Language="C#"
  Inherits="System.Web.Mvc.ViewPage<List<MovieEntityApp.Models.Movie>>" %>
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-
transitional.dtd">
<html xmlns="http://www.w3.org/1999/xhtml" >
<head runat="server">
    <title>Index</title>
</head>
<body>
    <div>

<% foreach (var m in ViewData.Model)
   { %>

    Title: <%= m.Title %>
    <br />
    Director: <%= m.Director %>
    <br />
    <%= Html.ActionLink("Edit", "Edit", new { id = m.Id })%>
    <%= Html.ActionLink("Delete", "Delete", new { id = m.Id })%>

        <hr />
<% } %>

<%= Html.ActionLink("Add Movie", "Add") %>

    </div>
</body>
</html>
```

The view in Listing 2 contains a **foreach** loop that iterates through each movie record and displays the values of the movie record's Title and Director properties. Notice that an Edit and Delete link is displayed next to each record. Furthermore, an Add Movie link appears at the bottom of the view (see Figure 7).

Figure 7 – The Index view

The Index view is a *typed view*. The Index view includes a <%@ Page %> directive with an *Inherits* attribute that casts the Model property to a strongly typed generic List collection of Movie objects (List<Movie).

Inserting Database Records with the Entity Framework

You can use the Entity Framework to make it easy to insert new records into a database table. Listing 3 contains two new actions added to the Home controller class that you can use to insert new records into the Movie database table.

Listing 3 – Controllers\HomeController.cs (Add methods)

```
public ActionResult Add()
{
    return View();
}

[AcceptVerbs(HttpVerbs.Post)]
public ActionResult Add(FormCollection form)
{
    var movieToAdd = new Movie();

    // Deserialize (Include white list!)
    TryUpdateModel(movieToAdd, new string[] { "Title", "Director" }, form.ToValueProvider());

    // Validate
    if (String.IsNullOrEmpty(movieToAdd.Title))
        ModelState.AddModelError("Title", "Title is required!");
    if (String.IsNullOrEmpty(movieToAdd.Director))
        ModelState.AddModelError("Director", "Director is required!");

    // If valid, save movie to database
    if (ModelState.IsValid)
    {
        _db.AddToMovieSet(movieToAdd);
        _db.SaveChanges();
        return RedirectToAction("Index");
    }

    // Otherwise, reshow form
    return View(movieToAdd);
}
```

The first Add() action simply returns a view. The view contains a form for adding a new movie database record (see Figure 8). When you submit the form, the second Add() action is invoked.

Notice that the second Add() action is decorated with the AcceptVerbs attribute. This action can be invoked only when performing an HTTP POST operation. In other words, this action can only be invoked when posting an HTML form.

The second Add() action creates a new instance of the Entity Framework Movie class with the help of the ASP.NET MVC TryUpdateModel() method. The TryUpdateModel() method takes the fields in the FormCollection passed to the Add() method and assigns the values of these HTML form fields to the Movie class.

When using the Entity Framework, you must supply a "white list" of properties when using the TryUpdateModel or UpdateModel methods to update the properties of an entity class.

Next, the Add() action performs some simple form validation. The action verifies that both the Title and Director properties have values. If there is a validation error, then a validation error message is added to ModelState.

If there are no validation errors then a new movie record is added to the Movies database table with the help of the Entity Framework. The new record is added to the database with the following two lines of code:

```
_db.AddToMovieSet(movieToAdd);
_db.SaveChanges();
```

The first line of code adds the new Movie entity to the set of movies being tracked by the Entity Framework. The

second line of code saves whatever changes have been made to the Movies being tracked back to the underlying database.

Figure 8 – The Add view

Updating Database Records with the Entity Framework

You can follow almost the same approach to edit a database record with the Entity Framework as the approach that we just followed to insert a new database record. Listing 4 contains two new controller actions named Edit(). The first Edit() action returns an HTML form for editing a movie record. The second Edit() action attempts to update the database.

Listing 4 – Controllers\HomeController.cs (Edit methods)

```
public ActionResult Edit(int id)
{
    // Get movie to update
    var movieToUpdate = _db.MovieSet.First(m => m.Id == id);

    ViewData.Model = movieToUpdate;
    return View();
}

[AcceptVerbs(HttpVerbs.Post)]
public ActionResult Edit(FormCollection form)
{
    // Get movie to update
    var id = Int32.Parse(form["id"]);
    var movieToUpdate = _db.MovieSet.First(m => m.Id == id);

    // Deserialize (Include white list!)
    TryUpdateModel(movieToUpdate, new string[] { "Title", "Director" }, form.ToValueProvider());

    // Validate
    if (String.IsNullOrEmpty(movieToUpdate.Title))
        ModelState.AddModelError("Title", "Title is required!");
    if (String.IsNullOrEmpty(movieToUpdate.Director))
        ModelState.AddModelError("Director", "Director is required!");

    // If valid, save movie to database
    if (ModelState.IsValid)
    {
        _db.SaveChanges();
        return RedirectToAction("Index");
    }

    // Otherwise, reshow form
    return View(movieToUpdate);
}
```

The second Edit() action starts by retrieving the Movie record from the database that matches the Id of the movie being edited. The following LINQ to Entities statement grabs the first database record that matches a particular Id:

```
var movieToUpdate = _db.MovieSet.First(m => m.Id == id);
```

Next, the TryUpdateModel() method is used to assign the values of the HTML form fields to the properties of the movie entity. Notice that a white list is supplied to specify the exact properties to update.

Next, some simple validation is performed to verify that both the Movie Title and Director properties have values. If either property is missing a value, then a validation error message is added to ModelState and ModelState.IsValid returns the value false.

Finally, if there are no validation errors, then the underlying Movies database table is updated with any changes by calling the SaveChanges() method.

When editing database records, you need to pass the Id of the record being edited to the controller action that performs the database update. Otherwise, the controller action will not know which record to update in the underlying database. The Edit view, contained in Listing 5, includes a hidden form field that represents the Id of the database record being edited.

Listing 5 – Views\Home\Edit.aspx

```
<%@ Page Language="C#"
  Inherits="System.Web.Mvc.ViewPage<MovieEntityApp.Models.Movie>" %>
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-
transitional.dtd">
<html xmlns="http://www.w3.org/1999/xhtml" >
<head runat="server">
    <title>Edit</title>
    <style type="text/css">

    .input-validation-error
    {
        background-color:Yellow;
    }

    </style>
</head>
<body>
    <div>

<h1>Edit Movie</h1>

<form method="post" action="/Home/Edit">

    <!-- Include Hidden Id -->
    <%= Html.Hidden("id") %>

    Title:
    <br />
    <%= Html.TextBox("title") %>

    <br /><br />
    Director:
    <br />
    <%= Html.TextBox("director") %>

    <br /><br />
    <input type="submit" value="Edit Movie" />
</form>

    </div>
</body>
</html>
```

Deleting Database Records with the Entity Framework

The final database operation, which we need to tackle in this tutorial, is deleting database records. You can use the controller action in Listing 6 to delete a particular database record.

Listing 6 -- \Controllers\HomeController.cs (Delete action)

```
public ActionResult Delete(int id)
{
    // Get movie to delete
    var movieToDelete = _db.MovieSet.First(m => m.Id == id);

    // Delete
    _db.DeleteObject(movieToDelete);
    _db.SaveChanges();

    // Show Index view
    return RedirectToAction("Index");
}
```

The Delete() action first retrieves the Movie entity that matches the Id passed to the action. Next, the movie is deleted from the database by calling the DeleteObject() method followed by the SaveChanges() method. Finally, the user is redirected back to the Index view.

Summary

The purpose of this tutorial was to demonstrate how you can build database-driven web applications by taking advantage of ASP.NET MVC and the Microsoft Entity Framework. You learned how to build an application that enables you to select, insert, update, and delete database records.

First, we discussed how you can use the Entity Data Model Wizard to generate an Entity Data Model from within Visual Studio. Next, you learn how to use LINQ to Entities to retrieve a set of database records from a database table. Finally, we used the Entity Framework to insert, update, and delete database records.

Creating Model Classes with LINQ to SQL (C#)

4/10/2020 • 11 minutes to read • Edit Online

by Microsoft

Download PDF

The goal of this tutorial is to explain one method of creating model classes for an ASP.NET MVC application. In this tutorial, you learn how to build model classes and perform database access by taking advantage of Microsoft LINQ to SQL.

The goal of this tutorial is to explain one method of creating model classes for an ASP.NET MVC application. In this tutorial, you learn how to build model classes and perform database access by taking advantage of Microsoft LINQ to SQL

In this tutorial, we build a basic Movie database application. We start by creating the Movie database application in the fastest and easiest way possible. We perform all of our data access directly from our controller actions.

Next, you learn how to use the Repository pattern. Using the Repository pattern requires a little more work. However, the advantage of adopting this pattern is that it enables you to build applications that are adaptable to change and can be easily tested.

What is a Model Class?

An MVC model contains all of the application logic that is not contained in an MVC view or MVC controller. In particular, an MVC model contains all of your application business and data access logic.

You can use a variety of different technologies to implement your data access logic. For example, you can build your data access classes using the Microsoft Entity Framework, NHibernate, Subsonic, or ADO.NET classes.

In this tutorial, I use LINQ to SQL to query and update the database. LINQ to SQL provides you with a very easy method of interacting with a Microsoft SQL Server database. However, it is important to understand that the ASP.NET MVC framework is not tied to LINQ to SQL in any way. ASP.NET MVC is compatible with any data access technology.

Create a Movie Database

In this tutorial -- in order to illustrate how you can build model classes -- we build a simple Movie database application. The first step is to create a new database. Right-click the App_Data folder in the Solution Explorer window and select the menu option **Add, New Item**. Select the **SQL Server Database** template, give it the name MoviesDB.mdf, and click the **Add** button (see Figure 1).

Figure 01: Adding a new SQL Server Database (Click to view full-size image)

After you create the new database, you can open the database by double-clicking the MoviesDB.mdf file in the App_Data folder. Double-clicking the MoviesDB.mdf file opens the Server Explorer window (see Figure 2).

The Server Explorer window is called the Database Explorer window when using Visual Web Developer.

Figure 02: Using the Server Explorer window (Click to view full-size image)

We need to add one table to our database that represents our movies. Right-click the Tables folder and select the menu option **Add New Table**. Selecting this menu option opens the Table Designer (see Figure 3).

Figure 03: The Table Designer (Click to view full-size image)

We need to add the following columns to our database table:

COLUMN NAME	DATA TYPE	ALLOW NULLS
Id	Int	False
Title	Nvarchar(200)	False
Director	Nvarchar(50)	False

You need to do two special things to the Id column. First, you need to mark the Id column as a primary key column by selecting the column in the Table Designer and clicking the icon of a key. LINQ to SQL requires you to specify your primary key columns when performing inserts or updates against the database.

Next, you need to mark the Id column as an Identity column by assigning the value Yes to the **Is Identity** property (see Figure 3). An Identity column is a column that is assigned a new number automatically whenever you add a new row of data to a table.

Create LINQ to SQL Classes

Our MVC model will contain LINQ to SQL classes that represent the tblMovie database table. The easiest way to create these LINQ to SQL classes is to right-click the Models folder, select **Add, New Item**, select the LINQ to SQL Classes template, give the classes the name Movie.dbml, and click the **Add** button (see Figure 4).

Figure 04: Creating LINQ to SQL classes (Click to view full-size image)

Immediately after you create the Movie LINQ to SQL Classes, the Object Relational Designer appears. You can drag database tables from the Server Explorer window onto the Object Relational Designer to create LINQ to SQL Classes that represent particular database tables. We need to add the tblMovie database table onto the Object Relational Designer (see Figure 5).

Figure 05: Using the Object Relational Designer (Click to view full-size image)

By default, the Object Relational Designer creates a class with the very same name as the database table that you drag onto the Designer. However, we don't want to call our class `tblMovie`. Therefore, click the name of the class in the Designer and change the name of the class to Movie.

Finally, remember to click the **Save** button (the picture of the floppy) to save the LINQ to SQL Classes. Otherwise, the LINQ to SQL Classes won't be generated by the Object Relational Designer.

Using LINQ to SQL in a Controller Action

Now that we have our LINQ to SQL classes, we can use these classes to retrieve data from the database. In this section, you learn how to use LINQ to SQL classes directly within a controller action. We'll display the list of movies from the tblMovies database table in an MVC view.

First, we need to modify the HomeController class. This class can be found in the Controllers folder of your application. Modify the class so it looks like the class in Listing 1.

Listing 1 – `Controllers\HomeController.cs`

```
using System.Linq;
using System.Web.Mvc;
using MvcApplication1.Models;

namespace MvcApplication1.Controllers
{
     [HandleError]
     public class HomeController : Controller
     {
          public ActionResult Index()
          {
               var dataContext = new MovieDataContext();
               var movies = from m in dataContext.Movies
                    select m;
               return View(movies);
          }
     }
}
```

The `Index()` action in Listing 1 uses a LINQ to SQL DataContext class (the `MovieDataContext`) to represent the `MoviesDB` database. The `MoveDataContext` class was generated by the Visual Studio Object Relational Designer.

A LINQ query is performed against the DataContext to retrieve all of the movies from the `tblMovies` database table. The list of movies is assigned to a local variable named `movies`. Finally, the list of movies is passed to the view through view data.

In order to show the movies, we next need to modify the Index view. You can find the Index view in the `Views\Home\` folder. Update the Index view so that it looks like the view in Listing 2.

Listing 2 – `Views\Home\Index.aspx`

```
<%@ Page Language="C#" MasterPageFile="~/Views/Shared/Site.Master" AutoEventWireup="true"
CodeBehind="Index.aspx.cs" Inherits="MvcApplication1.Views.Home.Index" %>
<%@ Import Namespace="MvcApplication1.Models" %>
<asp:Content ID="indexContent" ContentPlaceHolderID="MainContent" runat="server">

     <ul>
          <% foreach (Movie m in (IEnumerable)ViewData.Model)

          { %>
               <li> <%= m.Title %> </li>
          <% } %>
     </ul>
</asp:Content>
```

Notice that the modified Index view includes an `<%@ import namespace %>` directive at the top of the view. This directive imports the `MvcApplication1.Models namespace`. We need this namespace in order to work with the `model` classes – in particular, the `Movie` class -- in the view.

The view in Listing 2 contains a `foreach` loop that iterates through all of the items represented by the `ViewData.Model` property. The value of the `Title` property is displayed for each `movie`.

Notice that the value of the `ViewData.Model` property is cast to an `IEnumerable`. This is necessary in order to loop through the contents of `ViewData.Model`. Another option here is to create a strongly-typed `view`. When you create a strongly-typed `view`, you cast the `ViewData.Model` property to a particular type in a view's code-behind class.

If you run the application after modifying the `HomeController` class and the Index view then you will get a blank page. You'll get a blank page because there are no movie records in the `tblMovies` database table.

In order to add records to the `tblMovies` database table, right-click the `tblMovies` database table in the Server Explorer window (Database Explorer window in Visual Web Developer) and select the menu option Show Table Data. You can insert `movie` records by using the grid that appears (see Figure 6).

Figure 06: Inserting movies(Click to view full-size image)

After you add some database records to the `tblMovies` table, and you run the application, you'll see the page in Figure 7. All of the movie database records are displayed in a bulleted list.

Figure 07: Displaying movies with the Index view(Click to view full-size image)

Using the Repository Pattern

In the previous section, we used LINQ to SQL classes directly within a controller action. We used the `MovieDataContext` class directly from the `Index()` controller action. There is nothing wrong with doing this in the case of a simple application. However, working directly with LINQ to SQL in a controller class creates problems when you need to build a more complex application.

Using LINQ to SQL within a controller class makes it difficult to switch data access technologies in the future. For example, you might decide to switch from using Microsoft LINQ to SQL to using the Microsoft Entity Framework as your data access technology. In that case, you would need to rewrite every controller that accesses the database within your application.

Using LINQ to SQL within a controller class also makes it difficult to build unit tests for your application. Normally, you do not want to interact with a database when performing unit tests. You want to use your unit tests to test your application logic and not your database server.

In order to build an MVC application that is more adaptable to future change and that can be more easily tested, you should consider using the Repository pattern. When you use the Repository pattern, you create a separate repository class that contains all of your database access logic.

When you create the repository class, you create an interface that represents all of the methods used by the repository class. Within your controllers, you write your code against the interface instead of the repository. That way, you can implement the repository using different data access technologies in the future.

The interface in Listing 3 is named `IMovieRepository` and it represents a single method named `ListAll()`.

Listing 3 – `Models\IMovieRepository.cs`

```
using System.Collections.Generic;
namespace MvcApplication1.Models
{
    public interface IMovieRepository
    {
        IList<Movie> ListAll();
    }
}
```

The repository class in Listing 4 implements the `IMovieRepository` interface. Notice that it contains a method named `ListAll()` that corresponds to the method required by the `IMovieRepository` interface.

Listing 4 – `Models\MovieRepository.cs`

```
using System.Collections.Generic;
using System.Linq;

namespace MvcApplication1.Models
{
     public class MovieRepository : IMovieRepository
     {
          private MovieDataContext _dataContext;

          public MovieRepository()
          {
                _dataContext = new MovieDataContext();
          }

          #region IMovieRepository Members

          public IList<Movie> ListAll()
          {
               var movies = from m in _dataContext.Movies
                    select m;
               return movies.ToList();
          }

          #endregion
     }
}
```

Finally, the `MoviesController` class in Listing 5 uses the Repository pattern. It no longer uses LINQ to SQL classes directly.

Listing 5 – `Controllers\MoviesController.cs`

```
using System.Web.Mvc;
using MvcApplication1.Models;

namespace MvcApplication1.Controllers
{
     public class MoviesController : Controller
     {
          private IMovieRepository _repository;

          public MoviesController() : this(new MovieRepository())
          {
          }

          public MoviesController(IMovieRepository repository)
          {
               _repository = repository;
          }

          public ActionResult Index()
          {
               return View(_repository.ListAll());
          }
     }
}
```

Notice that the `MoviesController` class in Listing 5 has two constructors. The first constructor, the parameterless

constructor, is called when your application is running. This constructor creates an instance of the `MovieRepository` class and passes it to the second constructor.

The second constructor has a single parameter: an `IMovieRepository` parameter. This constructor simply assigns the value of the parameter to a class-level field named `_repository`.

The `MoviesController` class is taking advantage of a software design pattern called the Dependency Injection pattern. In particular, it is using something called Constructor Dependency Injection. You can read more about this pattern by reading the following article by Martin Fowler:

http://martinfowler.com/articles/injection.html

Notice that all of the code in the `MoviesController` class (with the exception of the first constructor) interacts with the `IMovieRepository` interface instead of the actual `MovieRepository` class. The code interacts with an abstract interface instead of a concrete implementation of the interface.

If you want to modify the data access technology used by the application then you can simply implement the `IMovieRepository` interface with a class that uses the alternative database access technology. For example, you could create an `EntityFrameworkMovieRepository` class or a `SubSonicMovieRepository` class. Because the controller class is programmed against the interface, you can pass a new implementation of `IMovieRepository` to the controller class and the class would continue to work.

Furthermore, if you want to test the `MoviesController` class, then you can pass a fake movie repository class to the `HomeController`. You can implement the `IMovieRepository` class with a class that does not actually access the database but contains all of the required methods of the `IMovieRepository` interface. That way, you can unit test the `MoviesController` class without actually accessing a real database.

Summary

The goal of this tutorial was to demonstrate how you can create MVC model classes by taking advantage of Microsoft LINQ to SQL. We examined two strategies for displaying database data in an ASP.NET MVC application. First, we created LINQ to SQL classes and used the classes directly within a controller action. Using LINQ to SQL classes within a controller enables you to quickly and easily display database data in an MVC application.

Next, we explored a slightly more difficult, but definitely more virtuous, path for displaying database data. We took advantage of the Repository pattern and placed all of our database access logic in a separate repository class. In our controller, we wrote all of our code against an interface instead of a concrete class. The advantage of the Repository pattern is that it enables us to easily change database access technologies in the future and it enables us to easily test our controller classes.

Displaying a Table of Database Data (C#)

4/10/2020 • 7 minutes to read • Edit Online

by Microsoft

Download PDF

> In this tutorial, I demonstrate two methods of displaying a set of database records. I show two methods of formatting a set of database records in an HTML table. First, I show how you can format the database records directly within a view. Next, I demonstrate how you can take advantage of partials when formatting database records.

The goal of this tutorial is to explain how you can display an HTML table of database data in an ASP.NET MVC application. First, you learn how to use the scaffolding tools included in Visual Studio to generate a view that displays a set of records automatically. Next, you learn how to use a partial as a template when formatting database records.

Create the Model Classes

We are going to display the set of records from the Movies database table. The Movies database table contains the following columns:

COLUMN NAME	DATA TYPE	ALLOW NULLS
Id	Int	False
Title	Nvarchar(200)	False
Director	NVarchar(50)	False
DateReleased	DateTime	False

In order to represent the Movies table in our ASP.NET MVC application, we need to create a model class. In this tutorial, we use the Microsoft Entity Framework to create our model classes.

> **NOTE**
> In this tutorial, we use the Microsoft Entity Framework. However, it is important to understand that you can use a variety of different technologies to interact with a database from an ASP.NET MVC application including LINQ to SQL, NHibernate, or ADO.NET.

Follow these steps to launch the Entity Data Model Wizard:

1. Right-click the Models folder in the Solution Explorer window and the select the menu option **Add, New Item**.
2. Select the **Data** category and select the **ADO.NET Entity Data Model** template.
3. Give your data model the name *MoviesDBModel.edmx* and click the **Add** button.

After you click the Add button, the Entity Data Model Wizard appears (see Figure 1). Follow these steps to complete the wizard:

1. In the **Choose Model Contents** step, select the **Generate from database** option.
2. In the **Choose Your Data Connection** step, use the *MoviesDB.mdf* data connection and the name *MoviesDBEntities* for the connection settings. Click the **Next** button.
3. In the **Choose Your Database Objects** step, expand the Tables node, select the Movies table. Enter the namespace *Models* and click the **Finish** button.

Figure 01: Creating LINQ to SQL classes (Click to view full-size image)

After you complete the Entity Data Model Wizard, the Entity Data Model Designer opens. The Designer should display the Movies entity (see Figure 2).

Figure 02: The Entity Data Model Designer (Click to view full-size image)

We need to make one change before we continue. The Entity Data Wizard generates a model class named *Movies* that represents the Movies database table. Because we'll use the Movies class to represent a particular movie, we need to modify the name of the class to be *Movie* instead of *Movies* (singular rather than plural).

Double-click the name of the class on the designer surface and change the name of the class from Movies to

Movie. After making this change, click the **Save** button (the icon of the floppy disk) to generate the Movie class.

Create the Movies Controller

Now that we have a way to represent our database records, we can create a controller that returns the collection of movies. Within the Visual Studio Solution Explorer window, right-click the Controllers folder and select the menu option **Add, Controller** (see Figure 3).

Figure 03: The Add Controller Menu (Click to view full-size image)

When the **Add Controller** dialog appears, enter the controller name MovieController (see Figure 4). Click the **Add** button to add the new controller.

Figure 04: The Add Controller dialog(Click to view full-size image)

We need to modify the Index() action exposed by the Movie controller so that it returns the set of database records. Modify the controller so that it looks like the controller in Listing 1.

Listing 1 – Controllers\MovieController.cs

```
using System.Linq;

using System.Web.Mvc;

using MvcApplication1.Models;

namespace MvcApplication1.Controllers

{

    public class MovieController : Controller

    {

        //

        // GET: /Movie/

        public ActionResult Index()

        {

            var entities = new MoviesDBEntities();

            return View(entities.MovieSet.ToList());

        }

    }

}
```

In Listing 1, the MoviesDBEntities class is used to represent the MoviesDB database. To use this class, you need to import the MvcApplication1.Models namespace like this:

using MvcApplication1.Models;

The expression *entities.MovieSet.ToList()* returns the set of all movies from the Movies database table.

Create the View

The easiest way to display a set of database records in an HTML table is to take advantage of the scaffolding provided by Visual Studio.

Build your application by selecting the menu option **Build, Build Solution**. You must build your application before opening the **Add View** dialog or your data classes won't appear in the dialog.

Right-click the Index() action and select the menu option **Add View** (see Figure 5).

Figure 05: Adding a view (Click to view full-size image)

In the **Add View** dialog, check the checkbox labeled **Create a strongly-typed view**. Select the Movie class as

the **view data class**. Select *List* as the **view content** (see Figure 6). Selecting these options will generate a strongly-typed view that displays a list of movies.

Figure 06: The Add View dialog(Click to view full-size image)

After you click the **Add** button, the view in Listing 2 is generated automatically. This view contains the code required to iterate through the collection of movies and display each of the properties of a movie.

Listing 2 – Views\Movie\Index.aspx

```
<%@ Page Title="" Language="C#" MasterPageFile="~/Views/Shared/Site.Master"
Inherits="System.Web.Mvc.ViewPage<IEnumerable<MvcApplication1.Models.Movie>>" %>

<asp:Content ID="Content1" ContentPlaceHolderID="TitleContent" runat="server">

      Index

</asp:Content>

<asp:Content ID="Content2" ContentPlaceHolderID="MainContent" runat="server">

    <h2>Index</h2>

    <table>

        <tr>

            <th></th>

            <th>

                Id

            </th>

            <th>

                Title

            </th>

            <th>

                Director

            </th>

            <th>
```

```
                DateReleased

            </th>

        </tr>

    <% foreach (var item in Model) { %>

        <tr>

            <td>

                <%= Html.ActionLink("Edit", "Edit", new { id=item.Id }) %> |

                <%= Html.ActionLink("Details", "Details", new { id=item.Id })%>

            </td>

            <td>

                <%= Html.Encode(item.Id) %>

            </td>

            <td>

                <%= Html.Encode(item.Title) %>

            </td>

            <td>

                <%= Html.Encode(item.Director) %>

            </td>

            <td>

                <%= Html.Encode(String.Format("{0:g}", item.DateReleased)) %>

            </td>

        </tr>

    <% } %>

    </table>

    <p>

        <%= Html.ActionLink("Create New", "Create") %>

    </p>

</asp:Content>
```

You can run the application by selecting the menu option **Debug, Start Debugging** (or hitting the F5 key). Running the application launches Internet Explorer. If you navigate to the /Movie URL then you'll see the page in Figure 7.

Figure 07: A table of movies(Click to view full-size image)

If you don't like anything about the appearance of the grid of database records in Figure 7 then you can simply modify the Index view. For example, you can change the *DateReleased* header to *Date Released* by modifying the Index view.

Create a Template with a Partial

When a view gets too complicated, it is a good idea to start breaking the view into partials. Using partials makes your views easier to understand and maintain. We'll create a partial that we can use as a template to format each of the movie database records.

Follow these steps to create the partial:

1. Right-click the Views\Movie folder and select the menu option **Add View**.
2. Check the checkbox labeled *Create a partial view (.ascx)*.
3. Name the partial *MovieTemplate*.
4. Check the checkbox labeled **Create a strongly-typed view**.
5. Select Movie as the *view data class*.
6. Select Empty as the *view content*.
7. Click the **Add** button to add the partial to your project.

After you complete these steps, modify the MovieTemplate partial to look like Listing 3.

Listing 3 – Views\Movie\MovieTemplate.ascx

```
<%@ Control Language="C#" Inherits="System.Web.Mvc.ViewUserControl<MvcApplication1.Models.Movie>" %>

<tr>

    <td>

        <%= Html.Encode(Model.Id) %>

    </td>

    <td>

        <%= Html.Encode(Model.Title) %>

    </td>

    <td>

        <%= Html.Encode(Model.Director) %>

    </td>

    <td>

        <%= Html.Encode(String.Format("{0:g}", Model.DateReleased)) %>

    </td>

</tr>
```

The partial in Listing 3 contains a template for a single row of records.

The modified Index view in Listing 4 uses the MovieTemplate partial.

Listing 4 – Views\Movie\Index.aspx

```
<%@ Page Title="" Language="C#" MasterPageFile="~/Views/Shared/Site.Master"
Inherits="System.Web.Mvc.ViewPage<IEnumerable<MvcApplication1.Models.Movie>>" %>

<asp:Content ID="Content2" ContentPlaceHolderID="MainContent" runat="server">

    <h2>Index</h2>

    <table>

        <tr>

            <th>

                Id

            </th>

            <th>

                Title

            </th>

            <th>

                Director

            </th>

            <th>

                DateReleased

            </th>

        </tr>

    <% foreach (var item in Model) { %>

        <% Html.RenderPartial("MovieTemplate", item); %>

    <% } %>

    </table>

</asp:Content>
```

The view in Listing 4 contains a foreach loop that iterates through all of the movies. For each movie, the MovieTemplate partial is used to format the movie. The MovieTemplate is rendered by calling the RenderPartial() helper method.

The modified Index view renders the very same HTML table of database records. However, the view has been greatly simplified.

The RenderPartial() method is different than most of the other helper methods because it does not return a string. Therefore, you must call the RenderPartial() method using <% Html.RenderPartial(); %> instead of <%= Html.RenderPartial(); %>.

Summary

The goal of this tutorial was to explain how you can display a set of database records in an HTML table. First, you learned how to return a set of database records from a controller action by taking advantage of the Microsoft Entity Framework. Next, you learned how to use Visual Studio scaffolding to generate a view that displays a

collection of items automatically. Finally, you learned how to simplify the view by taking advantage of a partial. You learned how to use a partial as a template so that you can format each database record.

Performing Simple Validation (C#)

2/20/2020 • 5 minutes to read • Edit Online

by Stephen Walther

> Learn how to perform validation in an ASP.NET MVC application. In this tutorial, Stephen Walther introduces you to model state and the validation HTML helpers.

The goal of this tutorial is to explain how you can perform validation within an ASP.NET MVC application. For example, you learn how to prevent someone from submitting a form that does not contain a value for a required field. You learn how to use model state and the validation HTML helpers.

Understanding Model State

You use model state - or more accurately, the model state dictionary - to represent validation errors. For example, the Create() action in Listing 1 validates the properties of a Product class before adding the Product class to a database.

I'm not recommending that you add your validation or database logic to a controller. A controller should contain only logic related to application flow control. We are taking a shortcut to keep things simple.

Listing 1 - Controllers\ProductController.cs

```
//
// POST: /Product/Create

[AcceptVerbs(HttpVerbs.Post)]
public ActionResult Create([Bind(Exclude="Id")] Product productToCreate)
{
    // Validation logic
    if (productToCreate.Name.Trim().Length == 0)
        ModelState.AddModelError("Name", "Name is required.");
    if (productToCreate.Description.Trim().Length == 0)
        ModelState.AddModelError("Description", "Description is required.");
    if (productToCreate.UnitsInStock
```

In Listing 1, the Name, Description, and UnitsInStock properties of the Product class are validated. If any of these properties fail a validation test then an error is added to the model state dictionary (represented by the ModelState property of the Controller class).

If there are any errors in model state then the ModelState.IsValid property returns false. In that case, the HTML form for creating a new product is redisplayed. Otherwise, if there are no validation errors, the new Product is added to the database.

Using the Validation Helpers

The ASP.NET MVC framework includes two validation helpers: the Html.ValidationMessage() helper and the Html.ValidationSummary() helper. You use these two helpers in a view to display validation error messages.

The Html.ValidationMessage() and Html.ValidationSummary() helpers are used in the Create and Edit views that are generated automatically by the ASP.NET MVC scaffolding. Follow these steps to generate the Create view:

1. Right-click the Create() action in the Product controller and select the menu option **Add View** (see Figure 1).

2. In the **Add View** dialog, check the checkbox labeled **Create a strongly-typed view** (see Figure 2).
3. From the **View data class** dropdown list, select the Product class.
4. From the **View content** dropdown list, select Create.
5. Click the **Add** button.

Make sure that you build your application before adding a view. Otherwise, the list of classes won't appear in the **View data class** dropdown list.

Figure 01: Adding a view(Click to view full-size image)

Figure 02: Creating a strongly-typed view (Click to view full-size image)

After you complete these steps, you get the Create view in Listing 2.

Listing 2 - Views\Product\Create.aspx

```
<%@ Page Title="" Language="C#" MasterPageFile="~/Views/Shared/Site.Master"
Inherits="System.Web.Mvc.ViewPage<MvcApplication1.Models.Product>" %>

<asp:Content ID="Content1" ContentPlaceHolderID="head" runat="server">
<title>Create</title>
</asp:Content>

<asp:Content ID="Content2" ContentPlaceHolderID="MainContent" runat="server">

    <h2>Create</h2>

    <%= Html.ValidationSummary() %>

    <% using (Html.BeginForm()) {%>

        <fieldset>
            <legend>Fields</legend>
            <p>
                <label for="Name">Name:</label>
                <%= Html.TextBox("Name") %>
                <%= Html.ValidationMessage("Name", "*") %>
            </p>
            <p>
                <label for="Description">Description:</label>
                <%= Html.TextBox("Description") %>
                <%= Html.ValidationMessage("Description", "*") %>
            </p>
            <p>
                <label for="Price">Price:</label>
                <%= Html.TextBox("Price") %>
                <%= Html.ValidationMessage("Price", "*") %>
            </p>
            <p>
                <label for="UnitsInStock">UnitsInStock:</label>
                <%= Html.TextBox("UnitsInStock") %>
                <%= Html.ValidationMessage("UnitsInStock", "*") %>
            </p>
            <p>
                <input type="submit" value="Create" />
            </p>
        </fieldset>

    <% } %>

    <div>
        <%=Html.ActionLink("Back to List", "Index") %>
    </div>

</asp:Content>
```

In Listing 2, the Html.ValidationSummary() helper is called immediately above the HTML form. This helper is used to display a list of validation error messages. The Html.ValidationSummary() helper renders the errors in a bulleted list.

The Html.ValidationMessage() helper is called next to each of the HTML form fields. This helper is used to display an error message right next to a form field. In the case of Listing 2, the Html.ValidationMessage() helper displays an asterisk when there is an error.

The page in Figure 3 illustrates the error messages rendered by the validation helpers when the form is submitted with missing fields and invalid values.

Figure 03: The Create view submitted with problems (Click to view full-size image)

Notice that the appearance of the HTML input fields are also modified when there is a validation error. The Html.TextBox() helper renders a *class="input-validation-error"* attribute when there is a validation error associated with the property rendered by the Html.TextBox() helper.

There are three cascading style sheet classes used to control the appearance of validation errors:

- input-validation-error - Applied to the <input> tag rendered by Html.TextBox() helper.
- field-validation-error - Applied to the tag rendered by the Html.ValidationMessage() helper.
- validation-summary-errors - Applied to the <ul> tag rendered by the Html.ValidationSummary() helper.

You can modify these cascading style sheet classes, and therefore modify the appearance of the validation errors, by modifying the Site.css file located in the Content folder.

> **NOTE**
>
> The HtmlHelper class includes read-only static properties for retrieving the names of the validation related CSS classes. These static properties are named ValidationInputCssClassName, ValidationFieldCssClassName, and ValidationSummaryCssClassName.

Prebinding Validation and Postbinding Validation

If you submit the HTML form for creating a Product, and you enter an invalid value for the price field and no value for the UnitsInStock field, then you'll get the validation messages displayed in Figure 4. Where do these validation error messages come from?

Figure 04: Prebinding Validation Errors(Click to view full-size image)

There are actually two types of validation error messages - those generated before the HTML form fields are bound to a class and those generated after the form fields are bound to the class. In other words, there are prebinding validation errors and postbinding validation errors.

The Create() action exposed by the Product controller in Listing 1 accepts an instance of the Product class. The signature of the Create method looks like this:

```
public ActionResult Create([Bind(Exclude="Id")] Product productToCreate)
```

The values of the HTML form fields from the Create form are bound to the productToCreate class by something called a model binder. The default model binder adds an error message to model state automatically when it cannot bind a form field to a form property.

The default model binder cannot bind the string "apple" to the Price property of the Product class. You can't assign a string to a decimal property. Therefore, the model binder adds an error to model state.

The default model binder also cannot assign a null value to a property that does not accept nulls. In particular, the model binder cannot assign a null value to the UnitsInStock property. Once again, the model binder gives up and adds an error message to model state.

If you want to customize the appearance of these prebinding error messages then you need to create resource strings for these messages.

Summary

The goal of this tutorial was to describe the basic mechanics of validation in the ASP.NET MVC framework. You learned how to use model state and the validation HTML helpers. We also discussed the distinction between prebinding and postbinding validation. In other tutorials, we'll discuss various strategies for moving your validation code out of your controllers and into your model classes.

Validating with the IDataErrorInfo Interface (C#)

2/20/2020 • 7 minutes to read • Edit Online

by Stephen Walther

> Stephen Walther shows you how to display custom validation error messages by implementing the IDataErrorInfo interface in a model class.

The goal of this tutorial is to explain one approach to performing validation in an ASP.NET MVC application. You learn how to prevent someone from submitting an HTML form without providing values for required form fields. In this tutorial, you learn how to perform validation by using the IErrorDataInfo interface.

Assumptions

In this tutorial, I'll use the MoviesDB database and the Movies database table. This table has the following columns:

COLUMN NAME	DATA TYPE	ALLOW NULLS
Id	Int	False
Title	Nvarchar(100)	False
Director	Nvarchar(100)	False
DateReleased	DateTime	False

In this tutorial, I use the Microsoft Entity Framework to generate my database model classes. The Movie class generated by the Entity Framework is displayed in Figure 1.

Figure 01: The Movie entity(Click to view full-size image)

> **NOTE**
>
> To learn more about using the Entity Framework to generate your database model classes, see my tutorial entitled Creating Model Classes with the Entity Framework.

The Controller Class

We use the Home controller to list movies and create new movies. The code for this class is contained in Listing 1.

Listing 1 - Controllers\HomeController.cs

```
using System.Linq;
using System.Web.Mvc;
using MvcApplication1.Models;

namespace MvcApplication1.Controllers
{

    public class HomeController : Controller
    {
        private MoviesDBEntities _db = new MoviesDBEntities();

        public ActionResult Index()
        {
            return View(_db.MovieSet.ToList());
        }

        public ActionResult Create()
        {
            return View();
        }

        [AcceptVerbs(HttpVerbs.Post)]
        public ActionResult Create([Bind(Exclude = "Id")] Movie movieToCreate)
        {
            // Validate
            if (!ModelState.IsValid)
                return View();

            // Add to database
            try
            {
                _db.AddToMovieSet(movieToCreate);
                _db.SaveChanges();

                return RedirectToAction("Index");
            }
            catch
            {
                return View();
            }
        }

    }
}
```

The Home controller class in Listing 1 contains two Create() actions. The first action displays the HTML form for creating a new movie. The second Create() action performs the actual insert of the new movie into the database. The second Create() action is invoked when the form displayed by the first Create() action is submitted to the server.

Notice that the second Create() action contains the following lines of code:

```
// Validate
if (!ModelState.IsValid)
    return View();
```

The IsValid property returns false when there is a validation error. In that case, the Create view that contains the HTML form for creating a movie is redisplayed.

Creating a Partial Class

The Movie class is generated by the Entity Framework. You can see the code for the Movie class if you expand the MoviesDBModel.edmx file in the Solution Explorer window and open the MoviesDBModel.Designer.cs file in the Code Editor (see Figure 2).

Figure 02: The code for the Movie entity(Click to view full-size image)

The Movie class is a partial class. That means that we can add another partial class with the same name to extend the functionality of the Movie class. We'll add our validation logic to the new partial class.

Add the class in Listing 2 to the Models folder.

Listing 2 - Models\Movie.cs

```
using System.Collections.Generic;
using System.ComponentModel;

namespace MvcApplication1.Models
{

    public partial class Movie
    {

    }
}
```

Notice that the class in Listing 2 includes the *partial* modifier. Any methods or properties that you add to this class become part of the Movie class generated by the Entity Framework.

Adding OnChanging and OnChanged Partial Methods

When the Entity Framework generates an entity class, the Entity Framework adds partial methods to the class automatically. The Entity Framework generates OnChanging and OnChanged partial methods that correspond to each property of the class.

In the case of the Movie class, the Entity Framework creates the following methods:

- OnIdChanging
- OnIdChanged
- OnTitleChanging
- OnTitleChanged
- OnDirectorChanging
- OnDirectorChanged

- OnDateReleasedChanging
- OnDateReleasedChanged

The OnChanging method is called right before the corresponding property is changed. The OnChanged method is called right after the property is changed.

You can take advantage of these partial methods to add validation logic to the Movie class. The update Movie class in Listing 3 verifies that the Title and Director properties are assigned nonempty values.

> **NOTE**
> A partial method is a method defined in a class that you are not required to implement. If you don't implement a partial method then the compiler removes the method signature and all calls to the method so there are no run-time costs associated with the partial method. In the Visual Studio Code Editor, you can add a partial method by typing the keyword *partial* followed by a space to view a list of partials to implement.

Listing 3 - Models\Movie.cs

```
using System.Collections.Generic;
using System.ComponentModel;

namespace MvcApplication1.Models
{

    public partial class Movie : IDataErrorInfo
    {
        private Dictionary<string, string> _errors = new Dictionary<string, string>();

        partial void OnTitleChanging(string value)
        {
            if (value.Trim().Length == 0)
                _errors.Add("Title", "Title is required.");
        }

        partial void OnDirectorChanging(string value)
        {
            if (value.Trim().Length == 0)
                _errors.Add("Director", "Director is required.");
        }

    }
}
```

For example, if you attempt to assign an empty string to the Title property, then an error message is assigned to a Dictionary named _errors.

At this point, nothing actually happens when you assign an empty string to the Title property and an error is added to the private _errors field. We need to implement the IDataErrorInfo interface to expose these validation errors to the ASP.NET MVC framework.

Implementing the IDataErrorInfo Interface

The IDataErrorInfo interface has been part of the .NET framework since the first version. This interface is a very simple interface:

```
public interface IDataErrorInfo
{
    string this[string columnName] { get; }

    string Error { get; }
}
```

If a class implements the IDataErrorInfo interface, the ASP.NET MVC framework will use this interface when creating an instance of the class. For example, the Home controller Create() action accepts an instance of the Movie class:

```
[AcceptVerbs(HttpVerbs.Post)]
public ActionResult Create([Bind(Exclude = "Id")] Movie movieToCreate)
{
    // Validate
    if (!ModelState.IsValid)
        return View();

    // Add to database
    try
    {
        _db.AddToMovieSet(movieToCreate);
        _db.SaveChanges();

        return RedirectToAction("Index");
    }
    catch
    {
        return View();
    }
}
```

The ASP.NET MVC framework creates the instance of the Movie passed to the Create() action by using a model binder (the DefaultModelBinder). The model binder is responsible for creating an instance of the Movie object by binding the HTML form fields to an instance of the Movie object.

The DefaultModelBinder detects whether or not a class implements the IDataErrorInfo interface. If a class implements this interface then the model binder invokes the IDataErrorInfo.this indexer for each property of the class. If the indexer returns an error message then the model binder adds this error message to model state automatically.

The DefaultModelBinder also checks the IDataErrorInfo.Error property. This property is intended to represent non-property specific validation errors associated with the class. For example, you might want to enforce a validation rule that depends on the values of multiple properties of the Movie class. In that case, you would return a validation error from the Error property.

The updated Movie class in Listing 4 implements the IDataErrorInfo interface.

Listing 4 - Models\Movie.cs (implements IDataErrorInfo)

```
using System.Collections.Generic;
using System.ComponentModel;

namespace MvcApplication1.Models
{

    public partial class Movie : IDataErrorInfo
    {
        private Dictionary<string, string> _errors = new Dictionary<string, string>();

        partial void OnTitleChanging(string value)
        {
            if (value.Trim().Length == 0)
                _errors.Add("Title", "Title is required.");
        }

        partial void OnDirectorChanging(string value)
        {
            if (value.Trim().Length == 0)
                _errors.Add("Director", "Director is required.");
        }

        #region IDataErrorInfo Members

        public string Error
        {
            get
            {
                return string.Empty;
            }
        }

        public string this[string columnName]
        {
            get
            {
                if (_errors.ContainsKey(columnName))
                    return _errors[columnName];
                return string.Empty;
            }
        }

        #endregion
    }
}
```

In Listing 4, the indexer property checks the _errors collection to see if it contains a key that corresponds to the property name passed to the indexer. If there is no validation error associated with the property then an empty string is returned.

You don't need to modify the Home controller in any way to use the modified Movie class. The page displayed in Figure 3 illustrates what happens when no value is entered for the Title or Director form fields.

Figure 03: A form with missing values (Click to view full-size image)

Notice that the DateReleased value is validated automatically. Because the DateReleased property does not accept NULL values, the DefaultModelBinder generates a validation error for this property automatically when it does not have a value. If you want to modify the error message for the DateReleased property then you need to create a custom model binder.

Summary

In this tutorial, you learned how to use the IDataErrorInfo interface to generate validation error messages. First, we created a partial Movie class that extends the functionality of the partial Movie class generated by the Entity Framework. Next, we added validation logic to the Movie class OnTitleChanging() and OnDirectorChanging() partial methods. Finally, we implemented the IDataErrorInfo interface in order to expose these validation messages to the ASP.NET MVC framework.

Validating with a Service Layer (C#)

2/20/2020 • 6 minutes to read • Edit Online

by Stephen Walther

Learn how to move your validation logic out of your controller actions and into a separate service layer. In this tutorial, Stephen Walther explains how you can maintain a sharp separation of concerns by isolating your service layer from your controller layer.

The goal of this tutorial is to describe one method of performing validation in an ASP.NET MVC application. In this tutorial, you learn how to move your validation logic out of your controllers and into a separate service layer.

Separating Concerns

When you build an ASP.NET MVC application, you should not place your database logic inside your controller actions. Mixing your database and controller logic makes your application more difficult to maintain over time. The recommendation is that you place all of your database logic in a separate repository layer.

For example, Listing 1 contains a simple repository named the ProductRepository. The product repository contains all of the data access code for the application. The listing also includes the IProductRepository interface that the product repository implements.

Listing 1 -- Models\ProductRepository.cs

```
using System.Collections.Generic;
using System.Linq;

namespace MvcApplication1.Models
{
    public class ProductRepository : MvcApplication1.Models.IProductRepository
    {
        private ProductDBEntities _entities = new ProductDBEntities();

        public IEnumerable<Product> ListProducts()
        {
            return _entities.ProductSet.ToList();
        }

        public bool CreateProduct(Product productToCreate)
        {
            try
            {
                _entities.AddToProductSet(productToCreate);
                _entities.SaveChanges();
                return true;
            }
            catch
            {
                return false;
            }
        }

    }

    public interface IProductRepository
    {
        bool CreateProduct(Product productToCreate);
        IEnumerable<Product> ListProducts();
    }

}
```

The controller in Listing 2 uses the repository layer in both its Index() and Create() actions. Notice that this controller does not contain any database logic. Creating a repository layer enables you to maintain a clean separation of concerns. Controllers are responsible for application flow control logic and the repository is responsible for data access logic.

Listing 2 - Controllers\ProductController.cs

```
using System.Web.Mvc;
using MvcApplication1.Models;

namespace MvcApplication1.Controllers
{
    public class ProductController : Controller
    {
        private IProductRepository _repository;

        public ProductController():
            this(new ProductRepository()) {}

        public ProductController(IProductRepository repository)
        {
            _repository = repository;
        }

        public ActionResult Index()
        {
            return View(_repository.ListProducts());
        }

        //
        // GET: /Product/Create

        public ActionResult Create()
        {
            return View();
        }

        //
        // POST: /Product/Create

        [AcceptVerbs(HttpVerbs.Post)]
        public ActionResult Create([Bind(Exclude="Id")] Product productToCreate)
        {
            _repository.CreateProduct(productToCreate);
            return RedirectToAction("Index");
        }

    }
}
```

Creating a Service Layer

So, application flow control logic belongs in a controller and data access logic belongs in a repository. In that case, where do you put your validation logic? One option is to place your validation logic in a *service layer*.

A service layer is an additional layer in an ASP.NET MVC application that mediates communication between a controller and repository layer. The service layer contains business logic. In particular, it contains validation logic.

For example, the product service layer in Listing 3 has a CreateProduct() method. The CreateProduct() method calls the ValidateProduct() method to validate a new product before passing the product to the product repository.

Listing 3 - Models\ProductService.cs

```
using System.Collections.Generic;
using System.Web.Mvc;

namespace MvcApplication1.Models
{
    public class ProductService : IProductService
    {

        private ModelStateDictionary _modelState;
        private IProductRepository _repository;

        public ProductService(ModelStateDictionary modelState, IProductRepository repository)
        {
            _modelState = modelState;
            _repository = repository;
        }

        protected bool ValidateProduct(Product productToValidate)
        {
            if (productToValidate.Name.Trim().Length == 0)
                _modelState.AddModelError("Name", "Name is required.");
            if (productToValidate.Description.Trim().Length == 0)
                _modelState.AddModelError("Description", "Description is required.");
            if (productToValidate.UnitsInStock < 0)
                _modelState.AddModelError("UnitsInStock", "Units in stock cannot be less than zero.");
            return _modelState.IsValid;
        }

        public IEnumerable<Product> ListProducts()
        {
            return _repository.ListProducts();
        }

        public bool CreateProduct(Product productToCreate)
        {
            // Validation logic
            if (!ValidateProduct(productToCreate))
                return false;

            // Database logic
            try
            {
                _repository.CreateProduct(productToCreate);
            }
            catch
            {
                return false;
            }
            return true;
        }

    }

    public interface IProductService
    {
        bool CreateProduct(Product productToCreate);
        IEnumerable<Product> ListProducts();
    }
}
```

The Product controller has been updated in Listing 4 to use the service layer instead of the repository layer. The controller layer talks to the service layer. The service layer talks to the repository layer. Each layer has a separate responsibility.

Listing 4 - Controllers\ProductController.cs

```
Listing 4 – Controllers\ProductController.cs
using System.Web.Mvc;
using MvcApplication1.Models;

namespace MvcApplication1.Controllers
{
    public class ProductController : Controller
    {
        private IProductService _service;

        public ProductController()
        {
            _service = new ProductService(this.ModelState, new ProductRepository());
        }

        public ProductController(IProductService service)
        {
            _service = service;
        }

        public ActionResult Index()
        {
            return View(_service.ListProducts());
        }

        //
        // GET: /Product/Create

        public ActionResult Create()
        {
            return View();
        }

        //
        // POST: /Product/Create

        [AcceptVerbs(HttpVerbs.Post)]
        public ActionResult Create([Bind(Exclude = "Id")] Product productToCreate)
        {
            if (!_service.CreateProduct(productToCreate))
                return View();
            return RedirectToAction("Index");
        }

    }
}
```

Notice that the product service is created in the product controller constructor. When the product service is created, the model state dictionary is passed to the service. The product service uses model state to pass validation error messages back to the controller.

Decoupling the Service Layer

We have failed to isolate the controller and service layers in one respect. The controller and service layers communicate through model state. In other words, the service layer has a dependency on a particular feature of the ASP.NET MVC framework.

We want to isolate the service layer from our controller layer as much as possible. In theory, we should be able to use the service layer with any type of application and not only an ASP.NET MVC application. For example, in the future, we might want to build a WPF front-end for our application. We should find a way to remove the dependency on ASP.NET MVC model state from our service layer.

In Listing 5, the service layer has been updated so that it no longer uses model state. Instead, it uses any class that

implements the IValidationDictionary interface.

Listing 5 - Models\ProductService.cs (decoupled)

```
using System.Collections.Generic;

namespace MvcApplication1.Models
{
    public class ProductService : IProductService
    {

        private IValidationDictionary _validatonDictionary;
        private IProductRepository _repository;

        public ProductService(IValidationDictionary validationDictionary, IProductRepository repository)
        {
            _validatonDictionary = validationDictionary;
            _repository = repository;
        }

        protected bool ValidateProduct(Product productToValidate)
        {
            if (productToValidate.Name.Trim().Length == 0)
                _validatonDictionary.AddError("Name", "Name is required.");
            if (productToValidate.Description.Trim().Length == 0)
                _validatonDictionary.AddError("Description", "Description is required.");
            if (productToValidate.UnitsInStock < 0)
                _validatonDictionary.AddError("UnitsInStock", "Units in stock cannot be less than zero.");
            return _validatonDictionary.IsValid;
        }

        public IEnumerable<Product> ListProducts()
        {
            return _repository.ListProducts();
        }

        public bool CreateProduct(Product productToCreate)
        {
            // Validation logic
            if (!ValidateProduct(productToCreate))
                return false;

            // Database logic
            try
            {
                _repository.CreateProduct(productToCreate);
            }
            catch
            {
                return false;
            }
            return true;
        }

    }

    public interface IProductService
    {
        bool CreateProduct(Product productToCreate);
        IEnumerable<Product> ListProducts();
    }
}
```

The IValidationDictionary interface is defined in Listing 6. This simple interface has a single method and a single property.

Listing 6 - Models\IValidationDictionary.cs

```
namespace MvcApplication1.Models
{
    public interface IValidationDictionary
    {
        void AddError(string key, string errorMessage);
        bool IsValid { get; }
    }
}
```

The class in Listing 7, named the ModelStateWrapper class, implements the IValidationDictionary interface. You can instantiate the ModelStateWrapper class by passing a model state dictionary to the constructor.

Listing 7 - Models\ModelStateWrapper.cs

```
using System.Web.Mvc;

namespace MvcApplication1.Models
{
    public class ModelStateWrapper : IValidationDictionary
    {

        private ModelStateDictionary _modelState;

        public ModelStateWrapper(ModelStateDictionary modelState)
        {
            _modelState = modelState;
        }

        #region IValidationDictionary Members

        public void AddError(string key, string errorMessage)
        {
            _modelState.AddModelError(key, errorMessage);
        }

        public bool IsValid
        {
            get { return _modelState.IsValid; }
        }

        #endregion
    }
}
```

Finally, the updated controller in Listing 8 uses the ModelStateWrapper when creating the service layer in its constructor.

Listing 8 - Controllers\ProductController.cs

```
using System.Web.Mvc;
using MvcApplication1.Models;

namespace MvcApplication1.Controllers
{
    public class ProductController : Controller
    {
        private IProductService _service;

        public ProductController()
        {
            _service = new ProductService(new ModelStateWrapper(this.ModelState), new ProductRepository());
        }

        public ProductController(IProductService service)
        {
            _service = service;
        }

        public ActionResult Index()
        {
            return View(_service.ListProducts());
        }

        //
        // GET: /Product/Create

        public ActionResult Create()
        {
            return View();
        }

        //
        // POST: /Product/Create

        [AcceptVerbs(HttpVerbs.Post)]
        public ActionResult Create([Bind(Exclude = "Id")] Product productToCreate)
        {
            if (!_service.CreateProduct(productToCreate))
                return View();
            return RedirectToAction("Index");
        }

    }
}
```

Using the IValidationDictionary interface and the ModelStateWrapper class enables us to completely isolate our service layer from our controller layer. The service layer is no longer dependent on model state. You can pass any class that implements the IValidationDictionary interface to the service layer. For example, a WPF application might implement the IValidationDictionary interface with a simple collection class.

Summary

The goal of this tutorial was to discuss one approach to performing validation in an ASP.NET MVC application. In this tutorial, you learned how to move all of your validation logic out of your controllers and into a separate service layer. You also learned how to isolate your service layer from your controller layer by creating a ModelStateWrapper class.

Validation with the Data Annotation Validators (C#)

4/10/2020 • 7 minutes to read • Edit Online

by Microsoft

> Take advantage of the Data Annotation Model Binder to perform validation within an ASP.NET MVC application. Learn how to use the different types of validator attributes and work with them in the Microsoft Entity Framework.

In this tutorial, you learn how to use the Data Annotation validators to perform validation in an ASP.NET MVC application. The advantage of using the Data Annotation validators is that they enable you to perform validation simply by adding one or more attributes – such as the Required or StringLength attribute – to a class property.

Before you can use the Data Annotation validators, you must download the Data Annotations Model Binder. You can download the Data Annotations Model Binder Sample from the CodePlex website by clicking here.

It is important to understand that the Data Annotations Model Binder is not an official part of the Microsoft ASP.NET MVC framework. Although the Data Annotations Model Binder was created by the Microsoft ASP.NET MVC team, Microsoft does not offer official product support for the Data Annotations Model Binder described and used in this tutorial.

Using the Data Annotation Model Binder

In order to use the Data Annotations Model Binder in an ASP.NET MVC application, you first need to add a reference to the Microsoft.Web.Mvc.DataAnnotations.dll assembly and the System.ComponentModel.DataAnnotations.dll assembly. Select the menu option **Project, Add Reference**. Next click the **Browse** tab and browse to the location where you downloaded (and unzipped) the Data Annotations Model Binder sample (see **Figure 1**).

Figure 1: Adding a reference to the Data Annotations Model Binder (Click to view full-size image)

Select both the Microsoft.Web.Mvc.DataAnnotations.dll assembly and the System.ComponentModel.DataAnnotations.dll assembly and click the **OK** button.

You cannot use the System.ComponentModel.DataAnnotations.dll assembly included with .NET Framework

Service Pack 1 with the Data Annotations Model Binder. You must use the version of the System.ComponentModel.DataAnnotations.dll assembly included with the Data Annotations Model Binder Sample download.

Finally, you need to register the DataAnnotations Model Binder in the Global.asax file. Add the following line of code to the Application_Start() event handler so that the Application_Start() method looks like this:

```
protected void Application_Start()
{
    RegisterRoutes(RouteTable.Routes);
    ModelBinders.Binders.DefaultBinder = new Microsoft.Web.Mvc.DataAnnotations.DataAnnotationsModelBinder();
}
```

This line of code registers the ataAnnotationsModelBinder as the default model binder for the entire ASP.NET MVC application.

Using the Data Annotation Validator Attributes

When you use the Data Annotations Model Binder, you use validator attributes to perform validation. The System.ComponentModel.DataAnnotations namespace includes the following validator attributes:

- Range – Enables you to validate whether the value of a property falls between a specified range of values.
- RegularExpression – Enables you to validate whether the value of a property matches a specified regular expression pattern.
- Required – Enables you to mark a property as required.
- StringLength – Enables you to specify a maximum length for a string property.
- Validation – The base class for all validator attributes.

> **NOTE**
> If your validation needs are not satisfied by any of the standard validators then you always have the option of creating a custom validator attribute by inheriting a new validator attribute from the base Validation attribute.

The Product class in **Listing 1** illustrates how to use these validator attributes. The Name, Description, and UnitPrice properties are marked as required. The Name property must have a string length that is less than 10 characters. Finally, the UnitPrice property must match a regular expression pattern that represents a currency amount.

```
using System.ComponentModel;
using System.ComponentModel.DataAnnotations;

namespace MvcApplication1.Models
{

    public class Product
    {
        public int Id { get; set; }

        [Required]
        [StringLength(10)]
        public string Name { get; set; }

        [Required]
        public string Description { get; set; }

        [DisplayName("Price")]
        [RegularExpression(@"^\$?\d+(\.(\d{2}))?$")]
        public decimal UnitPrice { get; set; }
    }
}
```

Listing 1: Models\Product.cs

The Product class illustrates how to use one additional attribute: the DisplayName attribute. The DisplayName attribute enables you to modify the name of the property when the property is displayed in an error message. Instead of displaying the error message "The UnitPrice field is required" you can display the error message "The Price field is required".

> **NOTE**
> If you want to completely customize the error message displayed by a validator then you can assign a custom error message to the validator's ErrorMessage property like this: `<Required(ErrorMessage:="This field needs a value!")>`

You can use the Product class in **Listing 1** with the Create() controller action in **Listing 2**. This controller action redisplays the Create view when model state contains any errors.

```
using System.Web.Mvc;
using MvcApplication1.Models;

namespace MvcApplication1.Controllers
{
    public class ProductController : Controller
    {
         //
        // GET: /Product/Create

        public ActionResult Create()
        {
            return View();
        }

        //
        // POST: /Product/Create

        [AcceptVerbs(HttpVerbs.Post)]
        public ActionResult Create([Bind(Exclude="Id")]Product productToCreate)
        {
            if (!ModelState.IsValid)
                return View();

            // TODO: Add insert logic here
            return RedirectToAction("Index");
        }

    }
}
```

Listing 2: Controllers\ProductController.vb

Finally, you can create the view in **Listing 3** by right-clicking the Create() action and selecting the menu option **Add View**. Create a strongly-typed view with the Product class as the model class. Select **Create** from the view content dropdown list (see **Figure 2**).

Figure 2: Adding the Create View

```
<%@ Page Title="" Language="C#" MasterPageFile="Views/Shared/Site.Master"
Inherits="System.Web.Mvc.ViewPage<MvcApplication1.Models.Product>" %>

<asp:Content ID="Content2" ContentPlaceHolderID="MainContent" runat="server">

    <h2>Create</h2>

    <%= Html.ValidationSummary("Create was unsuccessful. Please correct the errors and try again.") %>

    <% using (Html.BeginForm()) {%>

        <fieldset>
            <legend>Fields</legend>
            <p>
                <label for="Name">Name:</label>
                <%= Html.TextBox("Name") %>
                <%= Html.ValidationMessage("Name", "*") %>
            </p>
            <p>
                <label for="Description">Description:</label>
                <%= Html.TextBox("Description") %>
                <%= Html.ValidationMessage("Description", "*") %>
            </p>
            <p>
                <label for="UnitPrice">Price:</label>
                <%= Html.TextBox("UnitPrice") %>
                <%= Html.ValidationMessage("UnitPrice", "*") %>
            </p>
            <p>
                <input type="submit" value="Create" />
            </p>
        </fieldset>

    <% } %>

    <div>
        <%=Html.ActionLink("Back to List", "Index") %>
    </div>

</asp:Content>
```

Listing 3: Views\Product\Create.aspx

> **NOTE**
> Remove the Id field from the Create form generated by the **Add View** menu option. Because the Id field corresponds to an Identity column, you don't want to allow users to enter a value for this field.

If you submit the form for creating a Product and you do not enter values for the required fields, then the validation error messages in **Figure 3** are displayed.

Figure 3: Missing required fields

If you enter an invalid currency amount, then the error message in **Figure 4** is displayed.

Figure 4: Invalid currency amount

Using Data Annotation Validators with the Entity Framework

If you are using the Microsoft Entity Framework to generate your data model classes then you cannot apply the validator attributes directly to your classes. Because the Entity Framework Designer generates the model classes, any changes you make to the model classes will be overwritten the next time you make any changes in the Designer.

If you want to use the validators with the classes generated by the Entity Framework then you need to create meta data classes. You apply the validators to the meta data class instead of applying the validators to the actual class.

For example, imagine that you have created a Movie class using the Entity Framework (see **Figure 5**). Imagine, furthermore, that you want to make the Movie Title and Director properties required properties. In that case, you can create the partial class and meta data class in **Listing 4**.

Figure 5: Movie class generated by Entity Framework

```
using System.ComponentModel;
using System.ComponentModel.DataAnnotations;

namespace MvcApplication1.Models
{
    [MetadataType(typeof(MovieMetaData))]
    public partial class Movie
    {
    }

    public class MovieMetaData
    {
        [Required]
        public object Title { get; set; }

        [Required]
        [StringLength(5)]
        public object Director { get; set; }

        [DisplayName("Date Released")]
        [Required]
        public object DateReleased { get; set; }
    }

}
```

Listing 4: Models\Movie.cs

The file in **Listing 4** contains two classes named Movie and MovieMetaData. The Movie class is a partial class. It corresponds to the partial class generated by the Entity Framework that is contained in the DataModel.Designer.vb file.

Currently, the .NET framework does not support partial properties. Therefore, there is no way to apply the validator attributes to the properties of the Movie class defined in the DataModel.Designer.vb file by applying the validator attributes to the properties of the Movie class defined in the file in **Listing 4**.

Notice that the Movie partial class is decorated with a MetadataType attribute that points at the MovieMetaData class. The MovieMetaData class contains proxy properties for the properties of the Movie class.

The validator attributes are applied to the properties of the MovieMetaData class. The Title, Director, and DateReleased properties are all marked as required properties. The Director property must be assigned a string that contains less than 5 characters. Finally, the DisplayName attribute is applied to the DateReleased property to display an error message like "The Date Released field is required." instead of the error "The DateReleased field is required."

NOTE

Notice that the proxy properties in the MovieMetaData class do not need to represent the same types as the corresponding properties in the Movie class. For example, the Director property is a string property in the Movie class and an object property in the MovieMetaData class.

The page in **Figure 6** illustrates the error messages returned when you enter invalid values for the Movie properties.

Figure 6: Using validators with the Entity Framework (Click to view full-size image)

Summary

In this tutorial, you learned how to take advantage of the Data Annotation Model Binder to perform validation within an ASP.NET MVC application. You learned how to use the different types of validator attributes such as the Required and StringLength attributes. You also learned how to use these attributes when working with the Microsoft Entity Framework.

Creating Model Classes with the Entity Framework (VB)

4/10/2020 • 12 minutes to read • Edit Online

by Microsoft

> In this tutorial, you learn how to use ASP.NET MVC with the Microsoft Entity Framework. You learn how to use the Entity Wizard to create an ADO.NET Entity Data Model. Over the course of this tutorial, we build a web application that illustrates how to select, insert, update, and delete database data by using the Entity Framework.

The goal of this tutorial is to explain how you can create data access classes using the Microsoft Entity Framework when building an ASP.NET MVC application. This tutorial assumes no previous knowledge of the Microsoft Entity Framework. By the end of this tutorial, you'll understand how to use the Entity Framework to select, insert, update, and delete database records.

The Microsoft Entity Framework is an Object Relational Mapping (O/RM) tool that enables you to generate a data access layer from a database automatically. The Entity Framework enables you to avoid the tedious work of building your data access classes by hand.

> **NOTE**
> There is no essential connection between ASP.NET MVC and the Microsoft Entity Framework. There are several alternatives to the Entity Framework that you can use with ASP.NET MVC. For example, you can build your MVC Model classes using other O/RM tools such as Microsoft LINQ to SQL, NHibernate, or SubSonic.

In order to illustrate how you can use the Microsoft Entity Framework with ASP.NET MVC, we'll build a simple sample application. We'll create a Movie Database application that enables you to display and edit movie database records.

This tutorial assumes that you have Visual Studio 2008 or Visual Web Developer 2008 with Service Pack 1. You need Service Pack 1 in order to use the Entity Framework. You can download Visual Studio 2008 Service Pack 1 or Visual Web Developer with Service Pack 1 from the following address:

> https://www.asp.net/downloads/

Creating the Movie Sample Database

The Movie Database application uses a database table named Movies that contains the following columns:

COLUMN NAME	DATA TYPE	ALLOW NULLS?	IS PRIMARY KEY?
Id	int	False	True
Title	nvarchar(100)	False	False
Director	nvarchar(100)	False	False

You can add this table to an ASP.NET MVC project by following these steps:

1. Right-click the App_Data folder in the Solution Explorer window and select the menu option **Add, New Item.**
2. From the **Add New Item** dialog box, select **SQL Server Database**, give the database the name MoviesDB.mdf, and click the **Add** button.
3. Double-click the MoviesDB.mdf file to open the Server Explorer/Database Explorer window.
4. Expand the MoviesDB.mdf database connection, right-click the Tables folder, and select the menu option **Add New Table**.
5. In the Table Designer, add the Id, Title, and Director columns.
6. Click the **Save** button (it has the icon of the floppy) to save the new table with the name Movies.

After you create the Movies database table, you should add some sample data to the table. Right-click the Movies table and select the menu option **Show Table Data**. You can enter fake movie data into the grid that appears.

Creating the ADO.NET Entity Data Model

In order to use the Entity Framework, you need to create an Entity Data Model. You can take advantage of the Visual Studio *Entity Data Model Wizard* to generate an Entity Data Model from a database automatically.

Follow these steps:

1. Right-click the Models folder in the Solution Explorer window and select the menu option **Add, New Item**.
2. In the **Add New Item** dialog, select the Data category (see Figure 1).
3. Select the **ADO.NET Entity Data Model** template, give the Entity Data Model the name MoviesDBModel.edmx, and click the **Add** button. Clicking the **Add** button launches the Data Model Wizard.
4. In the **Choose Model Contents** step, choose the **Generate from a database** option and click the **Next** button (see Figure 2).
5. In the **Choose Your Data Connection** step, select the MoviesDB.mdf database connection, enter the entities connection settings name MoviesDBEntities, and click the **Next** button (see Figure 3).
6. In the **Choose Your Database Objects** step, select the Movie database table and click the **Finish** button (see Figure 4).

After you complete these steps, the ADO.NET Entity Data Model Designer (Entity Designer) opens.

Figure 1 – Creating a new Entity Data Model

Figure 2 – Choose Model Contents Step

Figure 3 – Choose Your Data Connection

Figure 4 – Choose Your Database Objects

Modifying the ADO.NET Entity Data Model

After you create an Entity Data Model, you can modify the model by taking advantage of the Entity Designer (see Figure 5). You can open the Entity Designer at any time by double-clicking the MoviesDBModel.edmx file contained in the Models folder within the Solution Explorer window.

Figure 5 – The ADO.NET Entity Data Model Designer

For example, you can use the Entity Designer to change the names of the classes that the Entity Model Data Wizard generates. The Wizard created a new data access class named Movies. In other words, the Wizard gave the class the very same name as the database table. Because we will use this class to represent a particular Movie instance, we should rename the class from Movies to Movie.

If you want to rename an entity class, you can double-click on the class name in the Entity Designer and enter a new name (see Figure 6). Alternatively, you can change the name of an entity in the Properties window after selecting an entity in the Entity Designer.

Figure 6 – Changing an entity name

Remember to save your Entity Data Model after making a modification by clicking the Save button (the icon of the floppy disk). Behind the scenes, the Entity Designer generates a set of Visual Basic .NET classes. You can view these classes by opening the MoviesDBModel.Designer.vb file from the Solution Explorer window.

Don't modify the code in the Designer.vb file since your changes will be overwritten the next time you use the Entity Designer. If you want to extend the functionality of the entity classes defined in the Designer.vb file then you can create *partial classes* in separate files.

Selecting Database Records with the Entity Framework

Let's start building our Movie Database application by creating a page that displays a list of movie records. The

Home controller in Listing 1 exposes an action named Index(). The Index() action returns all of the movie records from the Movie database table by taking advantage of the Entity Framework.

Listing 1 – Controllers\HomeController.vb

```
<HandleError()> _
Public Class HomeController
    Inherits System.Web.Mvc.Controller

    Private _db As MoviesDBEntities

    Public Sub New()
        _db = New MoviesDBEntities()
    End Sub

    Public Function Index()
        ViewData.Model = _db.MovieSet.ToList()
        Return View()
    End Function

End Class
```

Notice that the controller in Listing 1 includes a constructor. The constructor initializes a class-level field named _db. The _db field represents the database entities generated by the Microsoft Entity Framework. The _db field is an instance of the MoviesDBEntities class that was generated by the Entity Designer.

The _db field is used within the Index() action to retrieve the records from the Movies database table. The expression _db.MovieSet represents all of the records from the Movies database table. The ToList() method is used to convert the set of movies into a generic collection of Movie objects: List(Of Movie).

The movie records are retrieved with the help of LINQ to Entities. The Index() action in Listing 1 uses LINQ *method syntax* to retrieve the set of database records. If you prefer, you can use LINQ *query syntax* instead. The following two statements do the very same thing:

```
ViewData.Model = _db.MovieSet.ToList()
ViewData.Model = (from m in _db.MovieSet select m).ToList()
```

Use whichever LINQ syntax – method syntax or query syntax – that you find most intuitive. There is no difference in performance between the two approaches – the only difference is style.

The view in Listing 2 is used to display the movie records.

Listing 2 – Views\Home\Index.aspx

```
<%@ Page Language="VB"
  Inherits="System.Web.Mvc.ViewPage(Of List(Of MvcApplication1.Movie))" %>
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-
transitional.dtd">
<html xmlns="http://www.w3.org/1999/xhtml" >
<head runat="server">
    <title>Index</title>
</head>
<body>
    <div>

<%  For Each m In Model%>

    Title: <%= m.Title %>
    <br />
    Director: <%= m.Director %>
    <br />
    <%=Html.ActionLink("Edit", "Edit", New With {.id = m.Id})%>
    <%=Html.ActionLink("Delete", "Delete", New With {.id = m.Id})%>

        <hr />
<% Next%>

    <%= Html.ActionLink("Add Movie", "Add") %>

    </div>
</body>
</html>
```

The view in Listing 2 contains a **For Each** loop that iterates through each movie record and displays the values of the movie record's Title and Director properties. Notice that an Edit and Delete link is displayed next to each record. Furthermore, an Add Movie link appears at the bottom of the view (see Figure 7).

Figure 7 – The Index view

The Index view is a *typed view*. The Index view has a <%@ Page %> directive that includes an Inherits attribute. The Inherits attribute casts the ViewData.Model property to a strongly typed generic List collection of Movie objects – a List(Of Movie).

Inserting Database Records with the Entity Framework

You can use the Entity Framework to make it easy to insert new records into a database table. Listing 3 contains two new actions added to the Home controller class that you can use to insert new records into the Movie database table.

Listing 3 – Controllers\HomeController.vb (Add methods)

```
<HandleError()> _
Public Class HomeController
    Inherits System.Web.Mvc.Controller

    Public Function Add()
        Return View()
    End Function

    <AcceptVerbs(HttpVerbs.Post)> _
    Public Function Add(ByVal form As FormCollection)
        Dim movieToAdd As New Movie()

        ' Deserialize (Include white list!)
        TryUpdateModel(movieToAdd, New String() {"Title", "Director"}, form.ToValueProvider())

        ' Validate
        If String.IsNullOrEmpty(movieToAdd.Title) Then
            ModelState.AddModelError("Title", "Title is required!")
        End If
        If String.IsNullOrEmpty(movieToAdd.Director) Then
            ModelState.AddModelError("Director", "Director is required!")
        End If

        ' If valid, save movie to database
        If (ModelState.IsValid) Then
            _db.AddToMovieSet(movieToAdd)
            _db.SaveChanges()
            Return RedirectToAction("Index")
        End If

        ' Otherwise, reshow form
        Return View(movieToAdd)
    End Function

End Class
```

The first Add() action simply returns a view. The view contains a form for adding a new movie database record (see Figure 8). When you submit the form, the second Add() action is invoked.

Notice that the second Add() action is decorated with the AcceptVerbs attribute. This action can be invoked only when performing an HTTP POST operation. In other words, this action can only be invoked when posting an HTML form.

The second Add() action creates a new instance of the Entity Framework Movie class with the help of the ASP.NET MVC TryUpdateModel() method. The TryUpdateModel() method takes the fields in the FormCollection passed to the Add() method and assigns the values of these HTML form fields to the Movie class.

When using the Entity Framework, you must supply a "white list" of properties when using the TryUpdateModel or UpdateModel methods to update the properties of an entity class.

Next, the Add() action performs some simple form validation. The action verifies that both the Title and Director properties have values. If there is a validation error, then a validation error message is added to ModelState.

If there are no validation errors then a new movie record is added to the Movies database table with the help of the Entity Framework. The new record is added to the database with the following two lines of code:

```
_db.AddToMovieSet(movieToAdd)
_db.SaveChanges()
```

The first line of code adds the new Movie entity to the set of movies being tracked by the Entity Framework. The second line of code saves whatever changes have been made to the Movies being tracked back to the underlying database.

Figure 8 – The Add view

Updating Database Records with the Entity Framework

You can follow almost the same approach to edit a database record with the Entity Framework as the approach that we just followed to insert a new database record. Listing 4 contains two new controller actions named Edit(). The first Edit() action returns an HTML form for editing a movie record. The second Edit() action attempts to update the database.

Listing 4 – Controllers\HomeController.vb (Edit methods)

```
<HandleError()> _
Public Class HomeController
    Inherits System.Web.Mvc.Controller

    Public Function Edit(ByVal id As Integer)
        ' Get movie to update
        Dim movieToUpdate As Movie = _db.MovieSet.First(Function(m) m.Id = id)
        ViewData.Model = movieToUpdate
        Return View()
    End Function

    <AcceptVerbs(HttpVerbs.Post)> _
    Public Function Edit(ByVal form As FormCollection)

        ' Get movie to update
        Dim id As Integer = Integer.Parse(form("id"))
        Dim movieToUpdate As Movie = _db.MovieSet.First(Function(m) m.Id = id)

        ' Deserialize (Include white list!)
        TryUpdateModel(movieToUpdate, New String() {"Title", "Director"}, form.ToValueProvider)

        ' Validate
        If String.IsNullOrEmpty(movieToUpdate.Title) Then
            ModelState.AddModelError("Title", "Title is required!")
        End If
        If String.IsNullOrEmpty(movieToUpdate.Director) Then
            ModelState.AddModelError("Director", "Director is required!")
        End If

        ' If valid, save movie to database
        If (ModelState.IsValid) Then
            _db.SaveChanges()
            Return RedirectToAction("Index")
        End If

        ' Otherwise, reshow form
        Return View(movieToUpdate)
    End Function

End Class
```

The second Edit() action starts by retrieving the Movie record from the database that matches the Id of the movie being edited. The following LINQ to Entities statement grabs the first database record that matches a particular Id:

```
Dim movieToUpdate As Movie = _db.MovieSet.First(Function(m) m.Id = id)
```

Next, the TryUpdateModel() method is used to assign the values of the HTML form fields to the properties of the movie entity. Notice that a white list is supplied to specify the exact properties to update.

Next, some simple validation is performed to verify that both the Movie Title and Director properties have values. If either property is missing a value, then a validation error message is added to ModelState and ModelState.IsValid returns the value false.

Finally, if there are no validation errors, then the underlying Movies database table is updated with any changes by calling the SaveChanges() method.

When editing database records, you need to pass the Id of the record being edited to the controller action that performs the database update. Otherwise, the controller action will not know which record to update in the underlying database. The Edit view, contained in Listing 5, includes a hidden form field that represents the Id of the database record being edited.

Listing 5 – Views\Home\Edit.aspx

```
<%@ Page Language="VB" Inherits="System.Web.Mvc.ViewPage(Of MvcApplication1.Movie)" %>
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-
transitional.dtd">
<html xmlns="http://www.w3.org/1999/xhtml" >
<head id="Head1" runat="server">
    <title>Edit</title>
    <style type="text/css">

    .input-validation-error
    {
        background-color:Yellow;
    }

    </style>
</head>
<body>
    <div>

<h1>Edit Movie</h1>

<form method="post" action="/Home/Edit">

    <!-- Include Hidden Id -->
    <%= Html.Hidden("id") %>

    Title:
    <br />
    <%= Html.TextBox("title") %>

    <br /><br />
    Director:
    <br />
    <%= Html.TextBox("director") %>

    <br /><br />
    <input type="submit" value="Edit Movie" />
</form>

    </div>
</body>
</html>
```

Deleting Database Records with the Entity Framework

The final database operation, which we need to tackle in this tutorial, is deleting database records. You can use the controller action in Listing 6 to delete a particular database record.

Listing 6 -- \Controllers\HomeController.vb (Delete action)

```
<HandleError()> _
Public Class HomeController
    Inherits System.Web.Mvc.Controller

    Public Function Delete(ByVal id As Integer)
        ' Get movie to delete
        Dim movieToDelete As Movie = _db.MovieSet.First(Function(m) m.Id = id)

        ' Delete
        _db.DeleteObject(movieToDelete)
        _db.SaveChanges()

        ' Show Index view
        Return RedirectToAction("Index")
    End Function

End Class
```

The Delete() action first retrieves the Movie entity that matches the Id passed to the action. Next, the movie is deleted from the database by calling the DeleteObject() method followed by the SaveChanges() method. Finally, the user is redirected back to the Index view.

Summary

The purpose of this tutorial was to demonstrate how you can build database-driven web applications by taking advantage of ASP.NET MVC and the Microsoft Entity Framework. You learned how to build an application that enables you to select, insert, update, and delete database records.

First, we discussed how you can use the Entity Data Model Wizard to generate an Entity Data Model from within Visual Studio. Next, you learn how to use LINQ to Entities to retrieve a set of database records from a database table. Finally, we used the Entity Framework to insert, update, and delete database records.

Creating Model Classes with LINQ to SQL (VB)

4/10/2020 • 11 minutes to read • Edit Online

by Microsoft

Download PDF

The goal of this tutorial is to explain one method of creating model classes for an ASP.NET MVC application. In this tutorial, you learn how to build model classes and perform database access by taking advantage of Microsoft LINQ to SQL.

The goal of this tutorial is to explain one method of creating model classes for an ASP.NET MVC application. In this tutorial, you learn how to build model classes and perform database access by taking advantage of Microsoft LINQ to SQL.

In this tutorial, we build a basic Movie database application. We start by creating the Movie database application in the fastest and easiest way possible. We perform all of our data access directly from our controller actions.

Next, you learn how to use the Repository pattern. Using the Repository pattern requires a little more work. However, the advantage of adopting this pattern is that it enables you to build applications that are adaptable to change and can be easily tested.

What is a Model Class?

An MVC model contains all of the application logic that is not contained in an MVC view or MVC controller. In particular, an MVC model contains all of your application business and data access logic.

You can use a variety of different technologies to implement your data access logic. For example, you can build your data access classes using the Microsoft Entity Framework, NHibernate, Subsonic, or ADO.NET classes.

In this tutorial, I use LINQ to SQL to query and update the database. LINQ to SQL provides you with a very easy method of interacting with a Microsoft SQL Server database. However, it is important to understand that the ASP.NET MVC framework is not tied to LINQ to SQL in any way. ASP.NET MVC is compatible with any data access technology.

Create a Movie Database

In this tutorial -- in order to illustrate how you can build model classes -- we build a simple Movie database application. The first step is to create a new database. Right-click the App_Data folder in the Solution Explorer window and select the menu option **Add, New Item**. Select the SQL Server Database template, give it the name MoviesDB.mdf, and click the **Add** button (see Figure 1).

Figure 01: Adding a new SQL Server Database (Click to view full-size image)

After you create the new database, you can open the database by double-clicking the MoviesDB.mdf file in the App_Data folder. Double-clicking the MoviesDB.mdf file opens the Server Explorer window (see Figure 2).

	THE SERVER EXPLORER WINDOW IS CALLED THE DATABASE EXPLORER WINDOW WHEN USING VISUAL WEB DEVELOPER.

Figure 02: Using the Server Explorer window (Click to view full-size image)

We need to add one table to our database that represents our movies. Right-click the Tables folder and select the menu option **Add New Table**. Selecting this menu option opens the Table Designer (see Figure 3).

Figure 03: The Table Designer (Click to view full-size image)

We need to add the following columns to our database table:

COLUMN NAME	DATA TYPE	ALLOW NULLS
Id	Int	False
Title	Nvarchar(200)	False
Director	Nvarchar(50)	False

You need to do two special things to the Id column. First, you need to mark the Id column as a primary key column by selecting the column in the Table Designer and clicking the icon of a key. LINQ to SQL requires you to specify your primary key columns when performing inserts or updates against the database.

Next, you need to mark the Id column as an Identity column by assigning the value Yes to the **Is Identity** property (see Figure 3). An Identity column is a column that is assigned a new number automatically whenever you add a new row of data to a table.

After you make these changes, save the table with the name tblMovie. You can save the table by clicking the Save button.

Create LINQ to SQL Classes

Our MVC model will contain LINQ to SQL classes that represent the tblMovie database table. The easiest way to create these LINQ to SQL classes is to right-click the Models folder, select **Add, New Item**, select the LINQ to SQL Classes template, give the classes the name Movie.dbml, and click the **Add** button (see Figure 4).

Figure 04: Creating LINQ to SQL classes (Click to view full-size image)

Immediately after you create the Movie LINQ to SQL Classes, the Object Relational Designer appears. You can drag database tables from the Server Explorer window onto the Object Relational Designer to create LINQ to SQL Classes that represent particular database tables. We need to add the tblMovie database table onto the Object Relational Designer (see Figure 4).

Figure 05: Using the Object Relational Designer (Click to view full-size image)

By default, the Object Relational Designer creates a class with the very same name as the database table that you drag onto the Designer. However, we don't want to call our class tblMovie. Therefore, click the name of the class in the Designer and change the name of the class to Movie.

Finally, remember to click the **Save** button (the picture of the floppy) to save the LINQ to SQL Classes. Otherwise, the LINQ to SQL Classes won't be generated by the Object Relational Designer.

Using LINQ to SQL in a Controller Action

Now that we have our LINQ to SQL classes, we can use these classes to retrieve data from the database. In this section, you learn how to use LINQ to SQL classes directly within a controller action. We'll display the list of movies from the tblMovies database table in an MVC view.

First, we need to modify the HomeController class. This class can be found in the Controllers folder of your application. Modify the class so it looks like the class in Listing 1.

Listing 1 – `Controllers\HomeController.vb`

```
<HandleError()> _
Public Class HomeController

     Inherits System.Web.Mvc.Controller

     Function Index()
          Dim dataContext As New MovieDataContext()
          Dim movies = From m In dataContext.Movies _
               Select m
          return View(movies)
     End Function
End Class
```

The Index() action in Listing 1 uses a LINQ to SQL DataContext class (the MovieDataContext) to represent the MoviesDB database. The MoveDataContext class was generated by the Visual Studio Object Relational Designer.

A LINQ query is performed against the DataContext to retrieve all of the movies from the tblMovies database table. The list of movies is assigned to a local variable named movies. Finally, the list of movies is passed to the view through view data.

In order to show the movies, we next need to modify the Index view. You can find the Index view in the Views\Home\ folder. Update the Index view so that it looks like the view in Listing 2.

Listing 2 – `Views\Home\Index.aspx`

```
<%@ Page Language="VB" MasterPageFile="~/Views/Shared/Site.Master" AutoEventWireup="false"
CodeBehind="Index.aspx.vb" Inherits="MvcApplication1.Index" %>
<%@ Import Namespace="MvcApplication1" %>
<asp:Content ID="indexContent" ContentPlaceHolderID="MainContent" runat="server">

<ul>
<%  For Each m As Movie In ViewData.Model%>
    <li><%= m.Title %></li>
<% Next%>
</ul>
</asp:Content>
```

Notice that the modified Index view includes an <%@ import namespace %> directive at the top of the view. This directive imports the MvcApplication1 namespace. We need this namespace in order to work with the model classes – in particular, the Movie class -- in the view.

The view in Listing 2 contains a For Each loop that iterates through all of the items represented by the ViewData.Model property. The value of the Title property is displayed for each movie.

Notice that the value of the ViewData.Model property is cast to an IEnumerable. This is necessary in order to loop through the contents of ViewData.Model. Another option here is to create a strongly-typed view. When you create a strongly-typed view, you cast the ViewData.Model property to a particular type in a view's code-behind class.

If you run the application after modifying the HomeController class and the Index view then you will get a blank

page. You'll get a blank page because there are no movie records in the tblMovies database table.

In order to add records to the tblMovies database table, right-click the tblMovies database table in the Server Explorer window (Database Explorer window in Visual Web Developer) and select the menu option **Show Table Data**. You can insert movie records by using the grid that appears (see Figure 5).

Figure 06: Inserting movies(Click to view full-size image)

After you add some database records to the tblMovies table, and you run the application, you'll see the page in Figure 7. All of the movie database records are displayed in a bulleted list.

Figure 07: Displaying movies with the Index view(Click to view full-size image)

Using the Repository Pattern

In the previous section, we used LINQ to SQL classes directly within a controller action. We used the

MovieDataContext class directly from the Index() controller action. There is nothing wrong with doing this in the case of a simple application. However, working directly with LINQ to SQL in a controller class creates problems when you need to build a more complex application.

Using LINQ to SQL within a controller class makes it difficult to switch data access technologies in the future. For example, you might decide to switch from using Microsoft LINQ to SQL to using the Microsoft Entity Framework as your data access technology. In that case, you would need to rewrite every controller that accesses the database within your application.

Using LINQ to SQL within a controller class also makes it difficult to build unit tests for your application. Normally, you do not want to interact with a database when performing unit tests. You want to use your unit tests to test your application logic and not your database server.

In order to build an MVC application that is more adaptable to future change and that can be more easily tested, you should consider using the Repository pattern. When you use the Repository pattern, you create a separate repository class that contains all of your database access logic.

When you create the repository class, you create an interface that represents all of the methods used by the repository class. Within your controllers, you write your code against the interface instead of the repository. That way, you can implement the repository using different data access technologies in the future.

The interface in Listing 3 is named IMovieRepository and it represents a single method named ListAll().

Listing 3 – `Models\IMovieRepository.vb`

```
Public Interface IMovieRepository
     Function ListAll() As IList(Of Movie)
End Interface
```

The repository class in Listing 4 implements the IMovieRepository interface. Notice that it contains a method named ListAll() that corresponds to the method required by the IMovieRepository interface.

Listing 4 – `Models\MovieRepository.vb`

```
Public Class MovieRepository Implements IMovieRepository
         Private _dataContext As MovieDataContext

         Public Sub New()
              _dataContext = New MovieDataContext()
         End Sub

         Public Function ListAll() As IList(Of Movie) Implements IMovieRepository.ListAll
              Dim movies = From m In _dataContext.Movies _
                   Select m
              Return movies.ToList()
         End Function
End Class
```

Finally, the MoviesController class in Listing 5 uses the Repository pattern. It no longer uses LINQ to SQL classes directly.

Listing 5 – `Controllers\MoviesController.vb`

```
using System.Web.Mvc;
using MvcApplication1.Models;

namespace MvcApplication1.Controllers
{
    Public Class MoviesController
        Inherits System.Web.Mvc.Controller

             Private _repository As IMovieRepository

             Sub New()
                  Me.New(New MovieRepository())
             End Sub

             Sub New(ByVal repository As IMovieRepository)
                  _repository = repository
             End Sub

             Function Index()
                  Return View(_repository.ListAll())
             End Function
    End Class
}
```

Notice that the MoviesController class in Listing 5 has two constructors. The first constructor, the parameterless constructor, is called when your application is running. This constructor creates an instance of the MovieRepository class and passes it to the second constructor.

The second constructor has a single parameter: an IMovieRepository parameter. This constructor simply assigns the value of the parameter to a class-level field named _repository.

The MoviesController class is taking advantage of a software design pattern called the Dependency Injection pattern. In particular, it is using something called Constructor Dependency Injection. You can read more about this pattern by reading the following article by Martin Fowler:

http://martinfowler.com/articles/injection.html

Notice that all of the code in the MoviesController class (with the exception of the first constructor) interacts with the IMovieRepository interface instead of the actual MovieRepository class. The code interacts with an abstract interface instead of a concrete implementation of the interface.

If you want to modify the data access technology used by the application then you can simply implement the IMovieRepository interface with a class that uses the alternative database access technology. For example, you could create an EntityFrameworkMovieRepository class or a SubSonicMovieRepository class. Because the controller class is programmed against the interface, you can pass a new implementation of IMovieRepository to the controller class and the class would continue to work.

Furthermore, if you want to test the MoviesController class, then you can pass a fake movie repository class to the MoviesController. You can implement the IMovieRepository class with a class that does not actually access the database but contains all of the required methods of the IMovieRepository interface. That way, you can unit test the MoviesController class without actually accessing a real database.

Summary

The goal of this tutorial was to demonstrate how you can create MVC model classes by taking advantage of Microsoft LINQ to SQL. We examined two strategies for displaying database data in an ASP.NET MVC application. First, we created LINQ to SQL classes and used the classes directly within a controller action. Using LINQ to SQL classes within a controller enables you to quickly and easily display database data in an MVC application.

Next, we explored a slightly more difficult, but definitely more virtuous, path for displaying database data. We took

advantage of the Repository pattern and placed all of our database access logic in a separate repository class. In our controller, we wrote all of our code against an interface instead of a concrete class. The advantage of the Repository pattern is that it enables us to easily change database access technologies in the future and it enables us to easily test our controller classes.

Displaying a Table of Database Data (VB)

4/10/2020 • 7 minutes to read • Edit Online

by Microsoft

Download PDF

In this tutorial, I demonstrate two methods of displaying a set of database records. I show two methods of formatting a set of database records in an HTML table. First, I show how you can format the database records directly within a view. Next, I demonstrate how you can take advantage of partials when formatting database records.

The goal of this tutorial is to explain how you can display an HTML table of database data in an ASP.NET MVC application. First, you learn how to use the scaffolding tools included in Visual Studio to generate a view that displays a set of records automatically. Next, you learn how to use a partial as a template when formatting database records.

Create the Model Classes

We are going to display the set of records from the Movies database table. The Movies database table contains the following columns:

COLUMN NAME	DATA TYPE	ALLOW NULLS
Id	Int	False
Title	Nvarchar(200)	False
Director	NVarchar(50)	False
DateReleased	DateTime	False

In order to represent the Movies table in our ASP.NET MVC application, we need to create a model class. In this tutorial, we use the Microsoft Entity Framework to create our model classes.

> **NOTE**
> In this tutorial, we use the Microsoft Entity Framework. However, it is important to understand that you can use a variety of different technologies to interact with a database from an ASP.NET MVC application including LINQ to SQL, NHibernate, or ADO.NET.

Follow these steps to launch the Entity Data Model Wizard:

1. Right-click the Models folder in the Solution Explorer window and the select the menu option **Add, New Item**.
2. Select the **Data** category and select the **ADO.NET Entity Data Model** template.
3. Give your data model the name *MoviesDBModel.edmx* and click the **Add** button.

After you click the Add button, the Entity Data Model Wizard appears (see Figure 1). Follow these steps to complete the wizard:

1. In the **Choose Model Contents** step, select the **Generate from database** option.
2. In the **Choose Your Data Connection** step, use the *MoviesDB.mdf* data connection and the name *MoviesDBEntities* for the connection settings. Click the **Next** button.
3. In the **Choose Your Database Objects** step, expand the Tables node, select the Movies table. Enter the namespace *Models* and click the **Finish** button.

Figure 01: Creating LINQ to SQL classes (Click to view full-size image)

After you complete the Entity Data Model Wizard, the Entity Data Model Designer opens. The Designer should display the Movies entity (see Figure 2).

Figure 02: The Entity Data Model Designer (Click to view full-size image)

We need to make one change before we continue. The Entity Data Wizard generates a model class named *Movies* that represents the Movies database table. Because we'll use the Movies class to represent a particular movie, we need to modify the name of the class to be *Movie* instead of *Movies* (singular rather than plural).

Double-click the name of the class on the designer surface and change the name of the class from Movies to

Movie. After making this change, click the **Save** button (the icon of the floppy disk) to generate the Movie class.

Create the Movies Controller

Now that we have a way to represent our database records, we can create a controller that returns the collection of movies. Within the Visual Studio Solution Explorer window, right-click the Controllers folder and select the menu option **Add, Controller** (see Figure 3).

Figure 03: The Add Controller Menu (Click to view full-size image)

When the **Add Controller** dialog appears, enter the controller name MovieController (see Figure 4). Click the **Add** button to add the new controller.

Figure 04: The Add Controller dialog(Click to view full-size image)

We need to modify the Index() action exposed by the Movie controller so that it returns the set of database records. Modify the controller so that it looks like the controller in Listing 1.

Listing 1 – Controllers\MovieController.vb

```
Public Class MovieController

    Inherits System.Web.Mvc.Controller

    '

    ' GET: /Movie/

    Function Index() As ActionResult

        Dim entities As New MoviesDBEntities()

        Return View(entities.MovieSet.ToList())

    End Function

End Class
```

In Listing 1, the MoviesDBEntities class is used to represent the MoviesDB database. The expression *entities.MovieSet.ToList()* returns the set of all movies from the Movies database table.

Create the View

The easiest way to display a set of database records in an HTML table is to take advantage of the scaffolding provided by Visual Studio.

Build your application by selecting the menu option **Build, Build Solution**. You must build your application before opening the **Add View** dialog or your data classes won't appear in the dialog.

Right-click the Index() action and select the menu option **Add View** (see Figure 5).

Figure 05: Adding a view (Click to view full-size image)

In the **Add View** dialog, check the checkbox labeled **Create a strongly-typed view**. Select the Movie class as the **view data class**. Select *List* as the **view content** (see Figure 6). Selecting these options will generate a strongly-typed view that displays a list of movies.

Figure 06: The Add View dialog(Click to view full-size image)

After you click the **Add** button, the view in Listing 2 is generated automatically. This view contains the code required to iterate through the collection of movies and display each of the properties of a movie.

Listing 2 – Views\Movie\Index.aspx

```
<%@ Page Title="" Language="VB" MasterPageFile="~/Views/Shared/Site.Master"
Inherits="System.Web.Mvc.ViewPage(Of IEnumerable (Of MvcApplication1.Movie))" %>

<asp:Content ID="Content1" ContentPlaceHolderID="TitleContent" runat="server">

      Index

</asp:Content>
```

```
<asp:Content ID="Content2" ContentPlaceHolderID="MainContent" runat="server">

    <h2>Index</h2>

    <p>

        <%=Html.ActionLink("Create New", "Create")%>

    </p>

    <table>

        <tr>

            <th></th>

            <th>

                Id

            </th>

            <th>

                Title

            </th>

            <th>

                Director

            </th>

            <th>

                DateReleased

            </th>

        </tr>

    <% For Each item In Model%>

        <tr>

            <td>

                <%=Html.ActionLink("Edit", "Edit", New With {.id = item.Id})%> |

                <%=Html.ActionLink("Details", "Details", New With {.id = item.Id})%>

            </td>

            <td>

                <%= Html.Encode(item.Id) %>

            </td>

            <td>

                <%= Html.Encode(item.Title) %>

            </td>

            <td>

                <%= Html.Encode(item.Director) %>
```

```
            </td>

            <td>

                <%= Html.Encode(String.Format("{0:g}", item.DateReleased)) %>

            </td>

        </tr>

    <% Next%>

    </table>

</asp:Content>
```

You can run the application by selecting the menu option **Debug, Start Debugging** (or hitting the F5 key). Running the application launches Internet Explorer. If you navigate to the /Movie URL then you'll see the page in Figure 7.

Figure 07: A table of movies(Click to view full-size image)

If you don't like anything about the appearance of the grid of database records in Figure 7 then you can simply modify the Index view. For example, you can change the *DateReleased* header to *Date Released* by modifying the Index view.

Create a Template with a Partial

When a view gets too complicated, it is a good idea to start breaking the view into partials. Using partials makes your views easier to understand and maintain. We'll create a partial that we can use as a template to format each of the movie database records.

Follow these steps to create the partial:

1. Right-click the Views\Movie folder and select the menu option **Add View**.
2. Check the checkbox labeled *Create a partial view (.ascx)*.
3. Name the partial *MovieTemplate*.
4. Check the checkbox labeled **Create a strongly-typed view**.
5. Select Movie as the *view data class*.
6. Select Empty as the *view content*.

7. Click the **Add** button to add the partial to your project.

After you complete these steps, modify the MovieTemplate partial to look like Listing 3.

Listing 3 – Views\Movie\MovieTemplate.ascx

```
<%@ Control Language="VB" Inherits="System.Web.Mvc.ViewUserControl(Of MvcApplication1.Movie)" %>

<tr>

    <td>

        <%= Html.Encode(Model.Id) %>

    </td>

    <td>

        <%= Html.Encode(Model.Title) %>

    </td>

    <td>

        <%= Html.Encode(Model.Director) %>

    </td>

    <td>

        <%= Html.Encode(String.Format("{0:g}", Model.DateReleased)) %>

    </td>

</tr>
```

The partial in Listing 3 contains a template for a single row of records.

The modified Index view in Listing 4 uses the MovieTemplate partial.

Listing 4 – Views\Movie\Index.aspx

```
<%@ Page Title="" Language="VB" MasterPageFile="~/Views/Shared/Site.Master"
Inherits="System.Web.Mvc.ViewPage(Of IEnumerable (Of MvcApplication1.Movie))" %>

<asp:Content ID="Content2" ContentPlaceHolderID="MainContent" runat="server">

    <h2>Index</h2>

    <table>

        <tr>

            <th>

                Id

            </th>

            <th>

                Title

            </th>

            <th>

                Director

            </th>

            <th>

                DateReleased

            </th>

        </tr>

    <% For Each item In Model%>

        <% Html.RenderPartial("MovieTemplate", item)%>

    <% Next%>

    </table>

</asp:Content>
```

The view in Listing 4 contains a For Each loop that iterates through all of the movies. For each movie, the MovieTemplate partial is used to format the movie. The MovieTemplate is rendered by calling the RenderPartial() helper method.

The modified Index view renders the very same HTML table of database records. However, the view has been greatly simplified.

The RenderPartial() method is different than most of the other helper methods because it does not return a string. Therefore, you must call the RenderPartial() method using <% Html.RenderPartial() %> instead of <%= Html.RenderPartial() %>.

Summary

The goal of this tutorial was to explain how you can display a set of database records in an HTML table. First, you learned how to return a set of database records from a controller action by taking advantage of the Microsoft Entity Framework. Next, you learned how to use Visual Studio scaffolding to generate a view that displays a

collection of items automatically. Finally, you learned how to simplify the view by taking advantage of a partial. You learned how to use a partial as a template so that you can format each database record.

Performing Simple Validation (VB)

2/20/2020 • 5 minutes to read • Edit Online

by Stephen Walther

> Learn how to perform validation in an ASP.NET MVC application. In this tutorial, Stephen Walther introduces you to model state and the validation HTML helpers.

The goal of this tutorial is to explain how you can perform validation within an ASP.NET MVC application. For example, you learn how to prevent someone from submitting a form that does not contain a value for a required field. You learn how to use model state and the validation HTML helpers.

Understanding Model State

You use model state - or more accurately, the model state dictionary - to represent validation errors. For example, the Create() action in Listing 1 validates the properties of a Product class before adding the Product class to a database.

I'm not recommending that you add your validation or database logic to a controller. A controller should contain only logic related to application flow control. We are taking a shortcut to keep things simple.

Listing 1 - Controllers\ProductController.vb

```
'
' POST: /Product/Create

<AcceptVerbs(HttpVerbs.Post)> _
Public Function Create(<Bind(Exclude:="Id")> ByVal productToCreate As Product) As ActionResult
    ' Validation logic
    If productToCreate.Name.Trim().Length = 0 Then
    ModelState.AddModelError("Name", "Name is required.")
    End If
    If productToCreate.Description.Trim().Length = 0 Then
    ModelState.AddModelError("Description", "Description is required.")
    End If
    If productToCreate.UnitsInStock
```

In Listing 1, the Name, Description, and UnitsInStock properties of the Product class are validated. If any of these properties fail a validation test then an error is added to the model state dictionary (represented by the ModelState property of the Controller class).

If there are any errors in model state then the ModelState.IsValid property returns false. In that case, the HTML form for creating a new product is redisplayed. Otherwise, if there are no validation errors, the new Product is added to the database.

Using the Validation Helpers

The ASP.NET MVC framework includes two validation helpers: the Html.ValidationMessage() helper and the Html.ValidationSummary() helper. You use these two helpers in a view to display validation error messages.

The Html.ValidationMessage() and Html.ValidationSummary() helpers are used in the Create and Edit views that are generated automatically by the ASP.NET MVC scaffolding. Follow these steps to generate the Create view:

1. Right-click the Create() action in the Product controller and select the menu option **Add View** (see Figure 1).
2. In the **Add View** dialog, check the checkbox labeled **Create a strongly-typed view** (see Figure 2).
3. From the **View data class** dropdown list, select the Product class.
4. From the **View content** dropdown list, select Create.
5. Click the **Add** button.

Make sure that you build your application before adding a view. Otherwise, the list of classes won't appear in the **View data class** dropdown list.

Figure 01: Adding a view(Click to view full-size image)

Figure 02: Creating a strongly-typed view (Click to view full-size image)

After you complete these steps, you get the Create view in Listing 2.

Listing 2 - Views\Product\Create.aspx

```
<%@ Page Title="" Language="VB" MasterPageFile="~/Views/Shared/Site.Master"
Inherits="System.Web.Mvc.ViewPage(Of MvcApplication1.Product)" %>

<asp:Content ID="Content1" ContentPlaceHolderID="head" runat="server">
<title>Create</title>
</asp:Content>

<asp:Content ID="Content2" ContentPlaceHolderID="MainContent" runat="server">

    <h2>Create</h2>

    <%= Html.ValidationSummary() %>

    <% Using Html.BeginForm()%>

        <fieldset>
            <legend>Fields</legend>

            <p>
                <label for="Name">Name:</label>
                <%= Html.TextBox("Name") %>
                <%= Html.ValidationMessage("Name", "*") %>
            </p>
            <p>
                <label for="Description">Description:</label>
                <%= Html.TextBox("Description") %>
                <%= Html.ValidationMessage("Description", "*") %>
            </p>
            <p>
                <label for="Price">Price:</label>
                <%= Html.TextBox("Price") %>
                <%= Html.ValidationMessage("Price", "*") %>
            </p>
            <p>
                <label for="UnitsInStock">UnitsInStock:</label>
                <%= Html.TextBox("UnitsInStock") %>
                <%= Html.ValidationMessage("UnitsInStock", "*") %>
            </p>
            <p>
                <input type="submit" value="Create" />
            </p>
        </fieldset>

    <% End Using %>

    <div>
        <%=Html.ActionLink("Back to List", "Index") %>
    </div>

</asp:Content>
```

In Listing 2, the Html.ValidationSummary() helper is called immediately above the HTML form. This helper is used to display a list of validation error messages. The Html.ValidationSummary() helper renders the errors in a bulleted list.

The Html.ValidationMessage() helper is called next to each of the HTML form fields. This helper is used to display an error message right next to a form field. In the case of Listing 2, the Html.ValidationMessage() helper displays an asterisk when there is an error.

The page in Figure 3 illustrates the error messages rendered by the validation helpers when the form is submitted with missing fields and invalid values.

Figure 03: The Create view submitted with problems (Click to view full-size image)

Notice that the appearance of the HTML input fields are also modified when there is a validation error. The Html.TextBox() helper renders a *class="input-validation-error"* attribute when there is a validation error associated with the property rendered by the Html.TextBox() helper.

There are three cascading style sheet classes used to control the appearance of validation errors:

- input-validation-error - Applied to the <input> tag rendered by Html.TextBox() helper.
- field-validation-error - Applied to the tag rendered by the Html.ValidationMessage() helper.
- validation-summary-errors - Applied to the <ul> tag rendered by the Html.ValidationSummary() helper.

You can modify these cascading style sheet classes, and therefore modify the appearance of the validation errors, by modifying the Site.css file located in the Content folder.

> **NOTE**
>
> The HtmlHelper class includes read-only static properties for retrieving the names of the validation related CSS classes. These static properties are named ValidationInputCssClassName, ValidationFieldCssClassName, and ValidationSummaryCssClassName.

Prebinding Validation and Postbinding Validation

If you submit the HTML form for creating a Product, and you enter an invalid value for the price field and no value for the UnitsInStock field, then you'll get the validation messages displayed in Figure 4. Where do these validation error messages come from?

Figure 04: Prebinding Validation Errors(Click to view full-size image)

There are actually two types of validation error messages - those generated before the HTML form fields are bound to a class and those generated after the form fields are bound to the class. In other words, there are prebinding validation errors and postbinding validation errors.

The Create() action exposed by the Product controller in Listing 1 accepts an instance of the Product class. The signature of the Create method looks like this:

```
Public Function Create(<Bind(Exclude:="Id")> ByVal productToCreate As Product) As ActionResult
```

The values of the HTML form fields from the Create form are bound to the productToCreate class by something called a model binder. The default model binder adds an error message to model state automatically when it cannot bind a form field to a form property.

The default model binder cannot bind the string "apple" to the Price property of the Product class. You can't assign a string to a decimal property. Therefore, the model binder adds an error to model state.

The default model binder also cannot assign the value Nothing to a property that does not accept the value Nothing. In particular, the model binder cannot assign the value Nothing to the UnitsInStock property. Once again, the model binder gives up and adds an error message to model state.

If you want to customize the appearance of these prebinding error messages then you need to create resource strings for these messages.

Summary

The goal of this tutorial was to describe the basic mechanics of validation in the ASP.NET MVC framework. You learned how to use model state and the validation HTML helpers. We also discussed the distinction between prebinding and postbinding validation. In other tutorials, we'll discuss various strategies for moving your validation code out of your controllers and into your model classes.

Validating with the IDataErrorInfo Interface (VB)

2/20/2020 • 7 minutes to read • Edit Online

by Stephen Walther

> Stephen Walther shows you how to display custom validation error messages by implementing the IDataErrorInfo interface in a model class.

The goal of this tutorial is to explain one approach to performing validation in an ASP.NET MVC application. You learn how to prevent someone from submitting an HTML form without providing values for required form fields. In this tutorial, you learn how to perform validation by using the IErrorDataInfo interface.

Assumptions

In this tutorial, I'll use the MoviesDB database and the Movies database table. This table has the following columns:

COLUMN NAME	DATA TYPE	ALLOW NULLS
Id	Int	False
Title	Nvarchar(100)	False
Director	Nvarchar(100)	False
DateReleased	DateTime	False

In this tutorial, I use the Microsoft Entity Framework to generate my database model classes. The Movie class generated by the Entity Framework is displayed in Figure 1.

Figure 01: The Movie entity(Click to view full-size image)

> **NOTE**
>
> To learn more about using the Entity Framework to generate your database model classes, see my tutorial entitled Creating Model Classes with the Entity Framework.

The Controller Class

We use the Home controller to list movies and create new movies. The code for this class is contained in Listing 1.

Listing 1 - Controllers\HomeController.vb

```
Public Class HomeController
Inherits Controller

Private _db As New MoviesDBEntities()

Public Function Index() As ActionResult
    Return View(_db.MovieSet.ToList())
End Function

Public Function Create() As ActionResult
    Return View()
End Function

<AcceptVerbs(HttpVerbs.Post)> _
Public Function Create(<Bind(Exclude := "Id")> ByVal movieToCreate As Movie) As ActionResult
        ' Validate
        If (Not ModelState.IsValid) Then
        Return View()
        End If

    ' Add to database
    Try
        _db.AddToMovieSet(movieToCreate)
        _db.SaveChanges()

        Return RedirectToAction("Index")
    Catch
        Return View()
    End Try
End Function

End Class
```

The Home controller class in Listing 1 contains two Create() actions. The first action displays the HTML form for creating a new movie. The second Create() action performs the actual insert of the new movie into the database. The second Create() action is invoked when the form displayed by the first Create() action is submitted to the server.

Notice that the second Create() action contains the following lines of code:

```
' Validate
If (Not ModelState.IsValid) Then
Return View()
End If
```

The IsValid property returns false when there is a validation error. In that case, the Create view that contains the HTML form for creating a movie is redisplayed.

Creating a Partial Class

The Movie class is generated by the Entity Framework. You can see the code for the Movie class if you expand the MoviesDBModel.edmx file in the Solution Explorer window and open the MoviesDBModel.Designer.vb file in the Code Editor (see Figure 2).

Figure 02: The code for the Movie entity(Click to view full-size image)

The Movie class is a partial class. That means that we can add another partial class with the same name to extend the functionality of the Movie class. We'll add our validation logic to the new partial class.

Add the class in Listing 2 to the Models folder.

Listing 2 - Models\Movie.vb

```
Public Partial Class Movie

End Class
```

Notice that the class in Listing 2 includes the *partial* modifier. Any methods or properties that you add to this class become part of the Movie class generated by the Entity Framework.

Adding OnChanging and OnChanged Partial Methods

When the Entity Framework generates an entity class, the Entity Framework adds partial methods to the class automatically. The Entity Framework generates OnChanging and OnChanged partial methods that correspond to each property of the class.

In the case of the Movie class, the Entity Framework creates the following methods:

- OnIdChanging
- OnIdChanged
- OnTitleChanging
- OnTitleChanged
- OnDirectorChanging
- OnDirectorChanged
- OnDateReleasedChanging
- OnDateReleasedChanged

The OnChanging method is called right before the corresponding property is changed. The OnChanged method is called right after the property is changed.

You can take advantage of these partial methods to add validation logic to the Movie class. The update Movie class in Listing 3 verifies that the Title and Director properties are assigned nonempty values.

NOTE

A partial method is a method defined in a class that you are not required to implement. If you don't implement a partial method then the compiler removes the method signature and all calls to the method so there are no run-time costs associated with the partial method. In the Visual Studio Code Editor, you can add a partial method by typing the keyword *partial* followed by a space to view a list of partials to implement.

Listing 3 - Models\Movie.vb

```
Imports System.ComponentModel

Partial Public Class Movie
    Implements IDataErrorInfo

    Private _errors As New Dictionary(Of String, String)()

    Private Sub OnTitleChanging(ByVal value As String)
        If value.Trim().Length = 0 Then
            _errors.Add("Title", "Title is required.")
        End If
    End Sub

    Private Sub OnDirectorChanging(ByVal value As String)
        If value.Trim().Length = 0 Then
            _errors.Add("Director", "Director is required.")
        End If
    End Sub

End Class
```

For example, if you attempt to assign an empty string to the Title property, then an error message is assigned to a Dictionary named _errors.

At this point, nothing actually happens when you assign an empty string to the Title property and an error is added to the private _errors field. We need to implement the IDataErrorInfo interface to expose these validation errors to the ASP.NET MVC framework.

Implementing the IDataErrorInfo Interface

The IDataErrorInfo interface has been part of the .NET framework since the first version. This interface is a very simple interface:

```
Public Interface IDataErrorInfo
  Default ReadOnly Property Item(ByVal columnName As String) As String
  ReadOnly Property [Error]() As String
End Interface
```

If a class implements the IDataErrorInfo interface, the ASP.NET MVC framework will use this interface when creating an instance of the class. For example, the Home controller Create() action accepts an instance of the Movie class:

```
<AcceptVerbs(HttpVerbs.Post)> _
Public Function Create(<Bind(Exclude := "Id")> ByVal movieToCreate As Movie) As ActionResult
    ' Validate
    If (Not ModelState.IsValid) Then
        Return View()
    End If

    ' Add to database
    Try
        _db.AddToMovieSet(movieToCreate)
        _db.SaveChanges()

        Return RedirectToAction("Index")
    Catch
        Return View()
    End Try
End Function
```

The ASP.NET MVC framework creates the instance of the Movie passed to the Create() action by using a model binder (the DefaultModelBinder). The model binder is responsible for creating an instance of the Movie object by binding the HTML form fields to an instance of the Movie object.

The DefaultModelBinder detects whether or not a class implements the IDataErrorInfo interface. If a class implements this interface then the model binder invokes the IDataErrorInfo.this indexer for each property of the class. If the indexer returns an error message then the model binder adds this error message to model state automatically.

The DefaultModelBinder also checks the IDataErrorInfo.Error property. This property is intended to represent non-property specific validation errors associated with the class. For example, you might want to enforce a validation rule that depends on the values of multiple properties of the Movie class. In that case, you would return a validation error from the Error property.

The updated Movie class in Listing 4 implements the IDataErrorInfo interface.

Listing 4 - Models\Movie.vb (implements IDataErrorInfo)

```
Imports System.ComponentModel

Partial Public Class Movie
    Implements IDataErrorInfo

    Private _errors As New Dictionary(Of String, String)()

    Private Sub OnTitleChanging(ByVal value As String)
        If value.Trim().Length = 0 Then
            _errors.Add("Title", "Title is required.")
        End If
    End Sub

    Private Sub OnDirectorChanging(ByVal value As String)
        If value.Trim().Length = 0 Then
            _errors.Add("Director", "Director is required.")
        End If
    End Sub

#Region "IDataErrorInfo Members"

    Public ReadOnly Property [Error]() As String Implements IDataErrorInfo.Error
        Get
            Return String.Empty
        End Get
    End Property

    Default Public ReadOnly Property Item(ByVal columnName As String) As String Implements IDataErrorInfo.Item
        Get
            If _errors.ContainsKey(columnName) Then
                Return _errors(columnName)
            End If
            Return String.Empty
        End Get
    End Property

#End Region

End Class
```

In Listing 4, the indexer property checks the _errors collection to see if it contains a key that corresponds to the property name passed to the indexer. If there is no validation error associated with the property then an empty string is returned.

You don't need to modify the Home controller in any way to use the modified Movie class. The page displayed in Figure 3 illustrates what happens when no value is entered for the Title or Director form fields.

Figure 03: A form with missing values (Click to view full-size image)

Notice that the DateReleased value is validated automatically. Because the DateReleased property does not accept NULL values, the DefaultModelBinder generates a validation error for this property automatically when it does not have a value. If you want to modify the error message for the DateReleased property then you need to create a custom model binder.

Summary

In this tutorial, you learned how to use the IDataErrorInfo interface to generate validation error messages. First, we created a partial Movie class that extends the functionality of the partial Movie class generated by the Entity Framework. Next, we added validation logic to the Movie class OnTitleChanging() and OnDirectorChanging() partial methods. Finally, we implemented the IDataErrorInfo interface in order to expose these validation messages to the ASP.NET MVC framework.

Validating with a Service Layer (VB)

2/20/2020 • 6 minutes to read • Edit Online

by Stephen Walther

> Learn how to move your validation logic out of your controller actions and into a separate service layer. In this tutorial, Stephen Walther explains how you can maintain a sharp separation of concerns by isolating your service layer from your controller layer.

The goal of this tutorial is to describe one method of performing validation in an ASP.NET MVC application. In this tutorial, you learn how to move your validation logic out of your controllers and into a separate service layer.

Separating Concerns

When you build an ASP.NET MVC application, you should not place your database logic inside your controller actions. Mixing your database and controller logic makes your application more difficult to maintain over time. The recommendation is that you place all of your database logic in a separate repository layer.

For example, Listing 1 contains a simple repository named the ProductRepository. The product repository contains all of the data access code for the application. The listing also includes the IProductRepository interface that the product repository implements.

Listing 1 - Models\ProductRepository.vb

```
Public Class ProductRepository
Implements IProductRepository

    Private _entities As New ProductDBEntities()

Public Function ListProducts() As IEnumerable(Of Product) Implements IProductRepository.ListProducts
    Return _entities.ProductSet.ToList()
End Function

Public Function CreateProduct(ByVal productToCreate As Product) As Boolean Implements
IProductRepository.CreateProduct
    Try
        _entities.AddToProductSet(productToCreate)
        _entities.SaveChanges()
        Return True
    Catch
        Return False
    End Try
End Function

End Class

Public Interface IProductRepository
Function CreateProduct(ByVal productToCreate As Product) As Boolean
Function ListProducts() As IEnumerable(Of Product)
End Interface
```

The controller in Listing 2 uses the repository layer in both its Index() and Create() actions. Notice that this controller does not contain any database logic. Creating a repository layer enables you to maintain a clean separation of concerns. Controllers are responsible for application flow control logic and the repository is

responsible for data access logic.

Listing 2 - Controllers\ProductController.vb

```
Public Class ProductController
Inherits Controller

    Private _repository As IProductRepository

Public Sub New()
    Me.New(New ProductRepository())
End Sub

Public Sub New(ByVal repository As IProductRepository)
    _repository = repository
End Sub

Public Function Index() As ActionResult
    Return View(_repository.ListProducts())
End Function

'
' GET: /Product/Create

Public Function Create() As ActionResult
    Return View()
End Function

'
' POST: /Product/Create

<AcceptVerbs(HttpVerbs.Post)> _
Public Function Create(<Bind(Exclude:="Id")> ByVal productToCreate As Product) As ActionResult
    _repository.CreateProduct(productToCreate)
    Return RedirectToAction("Index")
End Function

End Class
```

Creating a Service Layer

So, application flow control logic belongs in a controller and data access logic belongs in a repository. In that case, where do you put your validation logic? One option is to place your validation logic in a *service layer*.

A service layer is an additional layer in an ASP.NET MVC application that mediates communication between a controller and repository layer. The service layer contains business logic. In particular, it contains validation logic.

For example, the product service layer in Listing 3 has a CreateProduct() method. The CreateProduct() method calls the ValidateProduct() method to validate a new product before passing the product to the product repository.

Listing 3 - Models\ProductService.vb

```
Public Class ProductService
Implements IProductService

Private _modelState As ModelStateDictionary
Private _repository As IProductRepository

Public Sub New(ByVal modelState As ModelStateDictionary, ByVal repository As IProductRepository)
    _modelState = modelState
    _repository = repository
End Sub

Protected Function ValidateProduct(ByVal productToValidate As Product) As Boolean
    If productToValidate.Name.Trim().Length = 0 Then
        _modelState.AddModelError("Name", "Name is required.")
    End If
    If productToValidate.Description.Trim().Length = 0 Then
        _modelState.AddModelError("Description", "Description is required.")
    End If
    If productToValidate.UnitsInStock
```

The Product controller has been updated in Listing 4 to use the service layer instead of the repository layer. The controller layer talks to the service layer. The service layer talks to the repository layer. Each layer has a separate responsibility.

Listing 4 - Controllers\ProductController.vb

```
Public Class ProductController
Inherits Controller

Private _service As IProductService

Public Sub New()
    _service = New ProductService(Me.ModelState, New ProductRepository())
End Sub

Public Sub New(ByVal service As IProductService)
    _service = service
End Sub

Public Function Index() As ActionResult
    Return View(_service.ListProducts())
End Function

'
' GET: /Product/Create

Public Function Create() As ActionResult
    Return View()
End Function

'
' POST: /Product/Create

<AcceptVerbs(HttpVerbs.Post)> _
Public Function Create(<Bind(Exclude := "Id")> ByVal productToCreate As Product) As ActionResult
    If Not _service.CreateProduct(productToCreate) Then
        Return View()
    End If
    Return RedirectToAction("Index")
End Function

End Class
```

Notice that the product service is created in the product controller constructor. When the product service is created, the model state dictionary is passed to the service. The product service uses model state to pass validation error messages back to the controller.

Decoupling the Service Layer

We have failed to isolate the controller and service layers in one respect. The controller and service layers communicate through model state. In other words, the service layer has a dependency on a particular feature of the ASP.NET MVC framework.

We want to isolate the service layer from our controller layer as much as possible. In theory, we should be able to use the service layer with any type of application and not only an ASP.NET MVC application. For example, in the future, we might want to build a WPF front-end for our application. We should find a way to remove the dependency on ASP.NET MVC model state from our service layer.

In Listing 5, the service layer has been updated so that it no longer uses model state. Instead, it uses any class that implements the IValidationDictionary interface.

Listing 5 - Models\ProductService.vb (decoupled)

```
Public Class ProductService
Implements IProductService

Private _validatonDictionary As IValidationDictionary
Private _repository As IProductRepository

Public Sub New(ByVal validationDictionary As IValidationDictionary, ByVal repository As IProductRepository)
    _validatonDictionary = validationDictionary
    _repository = repository
End Sub

Protected Function ValidateProduct(ByVal productToValidate As Product) As Boolean
    If productToValidate.Name.Trim().Length = 0 Then
        _validatonDictionary.AddError("Name", "Name is required.")
    End If
    If productToValidate.Description.Trim().Length = 0 Then
        _validatonDictionary.AddError("Description", "Description is required.")
    End If
    If productToValidate.UnitsInStock
```

The IValidationDictionary interface is defined in Listing 6. This simple interface has a single method and a single property.

Listing 6 - Models\IValidationDictionary.cs

```
Public Interface IValidationDictionary
Sub AddError(ByVal key As String, ByVal errorMessage As String)
ReadOnly Property IsValid() As Boolean
End Interface
```

The class in Listing 7, named the ModelStateWrapper class, implements the IValidationDictionary interface. You can instantiate the ModelStateWrapper class by passing a model state dictionary to the constructor.

Listing 7 - Models\ModelStateWrapper.vb

```
Public Class ModelStateWrapper
Implements IValidationDictionary

Private _modelState As ModelStateDictionary

Public Sub New(ByVal modelState As ModelStateDictionary)
    _modelState = modelState
End Sub

#Region "IValidationDictionary Members"

Public Sub AddError(ByVal key As String, ByVal errorMessage As String) Implements
IValidationDictionary.AddError
    _modelState.AddModelError(key, errorMessage)
End Sub

Public ReadOnly Property IsValid() As Boolean Implements IValidationDictionary.IsValid
    Get
        Return _modelState.IsValid
    End Get
End Property

#End Region

End Class
```

Finally, the updated controller in Listing 8 uses the ModelStateWrapper when creating the service layer in its constructor.

Listing 8 - Controllers\ProductController.vb

```
Public Class ProductController
Inherits Controller

Private _service As IProductService

Public Sub New()
    _service = New ProductService(New ModelStateWrapper(Me.ModelState), New ProductRepository())
End Sub

Public Sub New(ByVal service As IProductService)
    _service = service
End Sub

Public Function Index() As ActionResult
    Return View(_service.ListProducts())
End Function

'
' GET: /Product/Create

Public Function Create() As ActionResult
    Return View()
End Function

'
' POST: /Product/Create

<AcceptVerbs(HttpVerbs.Post)> _
Public Function Create(<Bind(Exclude := "Id")> ByVal productToCreate As Product) As ActionResult
    If Not _service.CreateProduct(productToCreate) Then
        Return View()
    End If
    Return RedirectToAction("Index")
End Function

End Class
```

Using the IValidationDictionary interface and the ModelStateWrapper class enables us to completely isolate our service layer from our controller layer. The service layer is no longer dependent on model state. You can pass any class that implements the IValidationDictionary interface to the service layer. For example, a WPF application might implement the IValidationDictionary interface with a simple collection class.

Summary

The goal of this tutorial was to discuss one approach to performing validation in an ASP.NET MVC application. In this tutorial, you learned how to move all of your validation logic out of your controllers and into a separate service layer. You also learned how to isolate your service layer from your controller layer by creating a ModelStateWrapper class.

Validation with the Data Annotation Validators (VB)

4/10/2020 • 8 minutes to read • Edit Online

by Microsoft

> Take advantage of the Data Annotation Model Binder to perform validation within an ASP.NET MVC application. Learn how to use the different types of validator attributes and work with them in the Microsoft Entity Framework.

In this tutorial, you learn how to use the Data Annotation validators to perform validation in an ASP.NET MVC application. The advantage of using the Data Annotation validators is that they enable you to perform validation simply by adding one or more attributes – such as the Required or StringLength attribute – to a class property.

Before you can use the Data Annotation validators, you must download the Data Annotations Model Binder. You can download the Data Annotations Model Binder Sample from the CodePlex website by clicking here.

It is important to understand that the Data Annotations Model Binder is not an official part of the Microsoft ASP.NET MVC framework. Although the Data Annotations Model Binder was created by the Microsoft ASP.NET MVC team, Microsoft does not offer official product support for the Data Annotations Model Binder described and used in this tutorial.

Using the Data Annotation Model Binder

In order to use the Data Annotations Model Binder in an ASP.NET MVC application, you first need to add a reference to the Microsoft.Web.Mvc.DataAnnotations.dll assembly and the System.ComponentModel.DataAnnotations.dll assembly. Select the menu option **Project, Add Reference**. Next click the **Browse** tab and browse to the location where you downloaded (and unzipped) the Data Annotations Model Binder sample (see **Figure 1**).

Figure 1: Adding a reference to the Data Annotations Model Binder (Click to view full-size image)

Select both the Microsoft.Web.Mvc.DataAnnotations.dll assembly and the System.ComponentModel.DataAnnotations.dll assembly and click the **OK** button.

You cannot use the System.ComponentModel.DataAnnotations.dll assembly included with .NET Framework

Service Pack 1 with the Data Annotations Model Binder. You must use the version of the System.ComponentModel.DataAnnotations.dll assembly included with the Data Annotations Model Binder Sample download.

Finally, you need to register the DataAnnotations Model Binder in the Global.asax file. Add the following line of code to the Application_Start() event handler so that the Application_Start() method looks like this:

```
Protected Sub Application_Start()
    RegisterRoutes(RouteTable.Routes)
    ModelBinders.Binders.DefaultBinder = New Microsoft.Web.Mvc.DataAnnotations.DataAnnotationsModelBinder()
End Sub
```

This line of code registers the DataAnnotationsModelBinder as the default model binder for the entire ASP.NET MVC application.

Using the Data Annotation Validator Attributes

When you use the Data Annotations Model Binder, you use validator attributes to perform validation. The System.ComponentModel.DataAnnotations namespace includes the following validator attributes:

- Range – Enables you to validate whether the value of a property falls between a specified range of values.
- RegularExpression – Enables you to validate whether the value of a property matches a specified regular expression pattern.
- Required – Enables you to mark a property as required.
- StringLength – Enables you to specify a maximum length for a string property.
- Validation – The base class for all validator attributes.

> **NOTE**
> If your validation needs are not satisfied by any of the standard validators then you always have the option of creating a custom validator attribute by inheriting a new validator attribute from the base Validation attribute.

The Product class in **Listing 1** illustrates how to use these validator attributes. The Name, Description, and UnitPrice properties are marked as required. The Name property must have a string length that is less than 10 characters. Finally, the UnitPrice property must match a regular expression pattern that represents a currency amount.

```
Imports System.ComponentModel
Imports System.ComponentModel.DataAnnotations

Public Class Product

    Private _id As Integer
    Private _name As String
    Private _description As String
    Private _unitPrice As Decimal

    Public Property Id() As Integer
        Get
            Return _id
        End Get
        Set(ByVal value As Integer)
            _id = value
        End Set
    End Property

     _
    Public Property Name() As String
        Get
            Return _name
        End Get
        Set(ByVal value As String)
            _name = value
        End Set
    End Property

     _
    Public Property Description() As String
        Get
            Return _description
        End Get
        Set(ByVal value As String)
            _description = value
        End Set
    End Property

     _
    Public Property UnitPrice() As Decimal
        Get
            Return _unitPrice
        End Get
        Set(ByVal value As Decimal)
            _unitPrice = value
        End Set
    End Property

End Class
```

Listing 1: Models\Product.vb

The Product class illustrates how to use one additional attribute: the DisplayName attribute. The DisplayName attribute enables you to modify the name of the property when the property is displayed in an error message. Instead of displaying the error message "The UnitPrice field is required" you can display the error message "The Price field is required".

> **NOTE**
>
> If you want to completely customize the error message displayed by a validator then you can assign a custom error message to the validator's ErrorMessage property like this: `<Required(ErrorMessage:="This field needs a value!")>`

You can use the Product class in **Listing 1** with the Create() controller action in **Listing 2**. This controller action redisplays the Create view when model state contains any errors.

```
Public Class ProductController
    Inherits System.Web.Mvc.Controller

    '
    ' GET: /Product/Create

    Function Create() As ActionResult
        Return View()
    End Function

    '
    ' POST: /Product/Create

     _
    Function Create( ByVal productToCreate As Product) As ActionResult

        If Not ModelState.IsValid Then
            Return View()
        End If

        Return RedirectToAction("Index")

    End Function

End Class
```

Listing 2: Controllers\ProductController.vb

Finally, you can create the view in **Listing 3** by right-clicking the Create() action and selecting the menu option **Add View**. Create a strongly-typed view with the Product class as the model class. Select **Create** from the view content dropdown list (see **Figure 2**).

Figure 2: Adding the Create View

```
<%@ Page Title="" Language="VB" MasterPageFile="~/Views/Shared/Site.Master"
Inherits="System.Web.Mvc.ViewPage(Of MvcApplication1.Product)" %>

<asp:Content ID="Content1" ContentPlaceHolderID="TitleContent" runat="server">
Create
</asp:Content>

<asp:Content ID="Content2" ContentPlaceHolderID="MainContent" runat="server">

    <h2>Create</h2>

    <%= Html.ValidationSummary("Create was unsuccessful. Please correct the errors and try again.") %>

    <% Using Html.BeginForm()%>

        <fieldset>
            <legend>Fields</legend>
            <p>
                <label for="Name">Name:</label>
                <%= Html.TextBox("Name") %>
                <%= Html.ValidationMessage("Name", "*") %>
            </p>
            <p>
                <label for="Description">Description:</label>
                <%= Html.TextBox("Description") %>
                <%= Html.ValidationMessage("Description", "*") %>
            </p>
            <p>
                <label for="UnitPrice">UnitPrice:</label>
                <%= Html.TextBox("UnitPrice") %>
                <%= Html.ValidationMessage("UnitPrice", "*") %>
            </p>
            <p>
                <input type="submit" value="Create" />
            </p>
        </fieldset>

    <% End Using %>

    <div>
        <%=Html.ActionLink("Back to List", "Index") %>
    </div>

</asp:Content>
```

Listing 3: Views\Product\Create.aspx

> **NOTE**
>
> Remove the Id field from the Create form generated by the **Add View** menu option. Because the Id field corresponds to an Identity column, you don't want to allow users to enter a value for this field.

If you submit the form for creating a Product and you do not enter values for the required fields, then the validation error messages in **Figure 3** are displayed.

Figure 3: Missing required fields

If you enter an invalid currency amount, then the error message in **Figure 4** is displayed.

Figure 4: Invalid currency amount

Using Data Annotation Validators with the Entity Framework

If you are using the Microsoft Entity Framework to generate your data model classes then you cannot apply the validator attributes directly to your classes. Because the Entity Framework Designer generates the model classes, any changes you make to the model classes will be overwritten the next time you make any changes in the Designer.

If you want to use the validators with the classes generated by the Entity Framework then you need to create meta data classes. You apply the validators to the meta data class instead of applying the validators to the actual class.

For example, imagine that you have created a Movie class using the Entity Framework (see **Figure 5**). Imagine, furthermore, that you want to make the Movie Title and Director properties required properties. In that case, you can create the partial class and meta data class in **Listing 4**.

Figure 5: Movie class generated by Entity Framework

```
Imports System.ComponentModel
Imports System.ComponentModel.DataAnnotations

 _
Partial Public Class Movie
End Class

Public Class MovieMetaData

    Private _title As Object
    Private _director As Object
    Private _dateReleased As Object

     _
    Public Property Title() As Object
        Get
            Return _title
        End Get
        Set(ByVal value As Object)
            _title = value
        End Set
    End Property

     _
    Public Property Director() As Object
        Get
            Return _director
        End Get
        Set(ByVal value As Object)
            _director = value
        End Set
    End Property

     _
    Public Property DateReleased() As Object
        Get
            Return _dateReleased
        End Get
        Set(ByVal value As Object)
            _dateReleased = value
        End Set
    End Property
End Class
```

Listing 4: Models\Movie.vb

The file in **Listing 4** contains two classes named Movie and MovieMetaData. The Movie class is a partial class. It corresponds to the partial class generated by the Entity Framework that is contained in the DataModel.Designer.vb file.

Currently, the .NET framework does not support partial properties. Therefore, there is no way to apply the

validator attributes to the properties of the Movie class defined in the DataModel.Designer.vb file by applying the validator attributes to the properties of the Movie class defined in the file in **Listing 4**.

Notice that the Movie partial class is decorated with a MetadataType attribute that points at the MovieMetaData class. The MovieMetaData class contains proxy properties for the properties of the Movie class.

The validator attributes are applied to the properties of the MovieMetaData class. The Title, Director, and DateReleased properties are all marked as required properties. The Director property must be assigned a string that contains less than 5 characters. Finally, the DisplayName attribute is applied to the DateReleased property to display an error message like "The Date Released field is required." instead of the error "The DateReleased field is required."

> **NOTE**
>
> Notice that the proxy properties in the MovieMetaData class do not need to represent the same types as the corresponding properties in the Movie class. For example, the Director property is a string property in the Movie class and an object property in the MovieMetaData class.

The page in **Figure 6** illustrates the error messages returned when you enter invalid values for the Movie properties.

Figure 6: Using validators with the Entity Framework (Click to view full-size image)

Summary

In this tutorial, you learned how to take advantage of the Data Annotation Model Binder to perform validation within an ASP.NET MVC application. You learned how to use the different types of validator attributes such as the Required and StringLength attributes. You also learned how to use these attributes when working with the Microsoft Entity Framework.

ASP.NET MVC Views Overview (C#)

2/20/2020 • 7 minutes to read • Edit Online

by Stephen Walther

> What is an ASP.NET MVC View and how does it differ from a HTML page? In this tutorial, Stephen Walther introduces you to Views and demonstrates how you can take advantage of View Data and HTML Helpers within a View.

The purpose of this tutorial is to provide you with a brief introduction to ASP.NET MVC views, view data, and HTML Helpers. By the end of this tutorial, you should understand how to create new views, pass data from a controller to a view, and use HTML Helpers to generate content in a view.

Understanding Views

For ASP.NET or Active Server Pages, ASP.NET MVC does not include anything that directly corresponds to a page. In an ASP.NET MVC application, there is not a page on disk that corresponds to the path in the URL that you type into the address bar of your browser. The closest thing to a page in an ASP.NET MVC application is something called a *view*.

In an ASP.NET MVC application, incoming browser requests are mapped to controller actions. A controller action might return a view. However, a controller action might perform some other type of action such as redirecting you to another controller action.

Listing 1 contains a simple controller named the HomeController. The HomeController exposes two controller actions named Index() and Details().

Listing 1 - HomeController.cs

```
using System.Web.Mvc;

namespace MvcApplication1.Controllers
{
    [HandleError]
    public class HomeController : Controller
    {
        public ActionResult Index()
        {
            return View();
        }

        public ActionResult Details()
        {
            return RedirectToAction("Index");
        }
    }
}
```

You can invoke the first action, the Index() action, by typing the following URL into your browser address bar:

/Home/Index

You can invoke the second action, the Details() action, by typing this address into your browser:

/Home/Details

The Index() action returns a view. Most actions that you create will return views. However, an action can return other types of action results. For example, the Details() action returns a RedirectToActionResult that redirects incoming request to the Index() action.

The Index() action contains the following single line of code:

View();

This line of code returns a view that must be located at the following path on your web server:

\Views\Home\Index.aspx

The path to the view is inferred from the name of the controller and the name of the controller action.

If you prefer, you can be explicit about the view. The following line of code returns a view named Fred :

View(Fred);

When this line of code is executed, a view is returned from the following path:

\Views\Home\Fred.aspx

> **NOTE**
> If you plan to create unit tests for your ASP.NET MVC application then it is a good idea to be explicit about view names. That way, you can create a unit test to verify that the expected view was returned by a controller action.

Adding Content to a View

A view is a standard (X)HTML document that can contain scripts. You use scripts to add dynamic content to a view.

For example, the view in Listing 2 displays the current date and time.

Listing 2 - \Views\Home\Index.aspx

```
<%@ Page Language="C#" Inherits="System.Web.Mvc.ViewPage" %>

<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-
transitional.dtd">

<html xmlns="http://www.w3.org/1999/xhtml" >
<head id="Head1" runat="server">
    <title>Index</title>
</head>
<body>
    <div>

    The current date and time is
    <% Response.Write(DateTime.Now);%>

    </div>
</body>
</html>
```

Notice that the body of the HTML page in Listing 2 contains the following script:

<% Response.Write(DateTime.Now);%>

You use the script delimiters <% and %> to mark the beginning and end of a script. This script is written in C#. It displays the current date and time by calling the Response.Write() method to render content to the browser. The script delimiters <% and %> can be used to execute one or more statements.

Since you call Response.Write() so often, Microsoft provides you with a shortcut for calling the Response.Write() method. The view in Listing 3 uses the delimiters <%= and %> as a shortcut for calling Response.Write().

Listing 3 - Views\Home\Index2.aspx

```
<%@ Page Language="C#" Inherits="System.Web.Mvc.ViewPage" %>

<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-
transitional.dtd">

<html xmlns="http://www.w3.org/1999/xhtml" >
<head id="Head1" runat="server">
    <title>Index</title>
</head>
<body>
    <div>

    The current date and time is
    <%=DateTime.Now %>

    </div>
</body>
</html>
```

You can use any .NET language to generate dynamic content in a view. Normally, you'll use either Visual Basic .NET or C# to write your controllers and views.

Using HTML Helpers to Generate View Content

To make it easier to add content to a view, you can take advantage of something called an *HTML Helper*. An HTML Helper, typically, is a method that generates a string. You can use HTML Helpers to generate standard HTML elements such as textboxes, links, dropdown lists, and list boxes.

For example, the view in Listing 4 takes advantage of three HTML Helpers -- the BeginForm(), the TextBox() and Password() helpers -- to generate a Login form (see Figure 1).

Listing 4 -- \Views\Home\Login.aspx

```
<%@ Page Language="C#" Inherits="System.Web.Mvc.ViewPage" %>

<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-
transitional.dtd">

<html xmlns="http://www.w3.org/1999/xhtml" >
<head id="Head1" runat="server">
    <title>Login Form</title>
</head>
<body>
    <div>

    <% using (Html.BeginForm())
       { %>

        <label for="UserName">User Name:</label>
        <br />
        <%= Html.TextBox("UserName") %>

        <br /><br />

        <label for="Password">Password:</label>
        <br />
        <%= Html.Password("Password") %>

        <br /><br />

        <input type="submit" value="Log in" />

    <% } %>

    </div>
</body>
</html>
```

Figure 01: A standard Login form (Click to view full-size image)

All of the HTML Helpers methods are called on the Html property of the view. For example, you render a TextBox by calling the Html.TextBox() method.

Notice that you use the script delimiters <%= and %> when calling both the Html.TextBox() and Html.Password() helpers. These helpers simply return a string. You need to call Response.Write() in order to render the string to the browser.

Using HTML Helper methods is optional. They make your life easier by reducing the amount of HTML and script that you need to write. The view in Listing 5 renders the exact same form as the view in Listing 4 without using

HTML Helpers.

Listing 5 -- \Views\Home\Login.aspx

```
<%@ Page Language="C#" AutoEventWireup="true" CodeBehind="Index4.aspx.cs" Inherits="MvcApp.Views.Home.Index4"
%>
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-
transitional.dtd">
<html xmlns="http://www.w3.org/1999/xhtml" >
<head id="Head1" runat="server">
    <title>Login Form without Help</title>
</head>
<body>
    <div>

    <form method="post" action="/Home/Login">

    <label for="userName">User Name:</label>
    <br />
    <input name="userName" />

    <br /><br />

    <label for="password">Password:</label>
    <br />
    <input name="password" type="password" />

    <br /><br />
    <input type="submit" value="Log In" />

    </form>

    </div>
</body>
</html>
```

You also have the option of creating your own HTML Helpers. For example, you can create a GridView() helper method that displays a set of database records in an HTML table automatically. We explore this topic in the tutorial **Creating Custom HTML Helpers**.

Using View Data to Pass Data to a View

You use view data to pass data from a controller to a view. Think of view data like a package that you send through the mail. All data passed from a controller to a view must be sent using this package. For example, the controller in Listing 6 adds a message to view data.

Listing 6 - ProductController.cs

```
using System.Web.Mvc;

namespace MvcApplication1.Controllers
{
    public class ProductController : Controller
    {
        public ActionResult Index()
        {
            ViewData["message"] = "Hello World!";
            return View();
        }

    }
}
```

The controller ViewData property represents a collection of name and value pairs. In Listing 6, the Index() method adds an item to the view data collection named message with the value Hello World!. When the view is returned by the Index() method, the view data is passed to the view automatically.

The view in Listing 7 retrieves the message from the view data and renders the message to the browser.

Listing 7 -- \Views\Product\Index.aspx

```
<%@ Page Language="C#" Inherits="System.Web.Mvc.ViewPage" %>

<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-
transitional.dtd">
<html xmlns="http://www.w3.org/1999/xhtml" >
<head id="Head1" runat="server">
    <title>Product Index</title>
</head>
<body>
    <div>

    <%= Html.Encode(ViewData["message"]) %>

    </div>
</body>
</html>
```

Notice that the view takes advantage of the Html.Encode() HTML Helper method when rendering the message. The Html.Encode() HTML Helper encodes special characters such as < and > into characters that are safe to display in a web page. Whenever you render content that a user submits to a website, you should encode the content to prevent JavaScript injection attacks.

(Because we created the message ourselves in the ProductController, we don't really need to encode the message. However, it is a good habit to always call the Html.Encode() method when displaying content retrieved from view data within a view.)

In Listing 7, we took advantage of view data to pass a simple string message from a controller to a view. You also can use view data to pass other types of data, such as a collection of database records, from a controller to a view. For example, if you want to display the contents of the Products database table in a view, then you would pass the collection of database records in view data.

You also have the option of passing strongly typed view data from a controller to a view. We explore this topic in the tutorial **Understanding Strongly Typed View Data and Views**.

Summary

This tutorial provided a brief introduction to ASP.NET MVC views, view data, and HTML Helpers. In the first section, you learned how to add new views to your project. You learned that you must add a view to the right folder in order to call it from a particular controller. Next, we discussed the topic of HTML Helpers. You learned how HTML Helpers enable you to easily generate standard HTML content. Finally, you learned how to take advantage of view data to pass data from a controller to a view.

The goal of this tutorial is to demonstrate how you can create custom HTML Helpers that you can use within your MVC views. By taking advantage of HTML Helpers, you can reduce the amount of tedious typing of HTML tags that you must perform to create a standard HTML page.

In the first part of this tutorial, I describe some of the existing HTML Helpers included with the ASP.NET MVC framework. Next, I describe two methods of creating custom HTML Helpers: I explain how to create custom HTML Helpers by creating a static method and by creating an extension method.

Understanding HTML Helpers

An HTML Helper is just a method that returns a string. The string can represent any type of content that you want. For example, you can use HTML Helpers to render standard HTML tags like HTML `<input>` and `<img>` tags. You also can use HTML Helpers to render more complex content such as a tab strip or an HTML table of database data.

The ASP.NET MVC framework includes the following set of standard HTML Helpers (this is not a complete list):

- Html.ActionLink()
- Html.BeginForm()
- Html.CheckBox()
- Html.DropDownList()
- Html.EndForm()
- Html.Hidden()
- Html.ListBox()
- Html.Password()
- Html.RadioButton()
- Html.TextArea()
- Html.TextBox()

For example, consider the form in Listing 1. This form is rendered with the help of two of the standard HTML Helpers (see Figure 1). This form uses the `Html.BeginForm()` and `Html.TextBox()` Helper methods to render a simple HTML form.

Figure 01: Page rendered with HTML Helpers (Click to view full-size image)

Listing 1 – `Views\Home\Index.aspx`

```
<%@ Page Language="C#" AutoEventWireup="true" CodeBehind="Index.aspx.cs"
Inherits="MvcApplication1.Views.Home.Index"%>
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-
transitional.dtd">

<html xmlns= "http://www.w3.org/1999/xhtml ">
<head id="Head1" runat="server">
     <title>Index</title>
</head>
<body>
      <div>
          <% using (Html.BeginForm())
          { %>

               <label for="firstName">First Name:</label>
               <br />
               <%= Html.TextBox("firstName")%>
               <br /><br />
               <label for="lastName">Last Name:</label>
               <br />

               <%= Html.TextBox("lastName")%>
               <br /><br />
               <input type="submit" value="Register" />
          <% } %>
     1     </div>
</body>
</html>
```

The Html.BeginForm() Helper method is used to create the opening and closing HTML `<form>` tags. Notice that the `Html.BeginForm()` method is called within a using statement. The using statement ensures that the `<form>` tag gets closed at the end of the using block.

If you prefer, instead of creating a using block, you can call the Html.EndForm() Helper method to close the `<form>` tag. Use whichever approach to creating an opening and closing `<form>` tag that seems most intuitive to you.

The `Html.TextBox()` Helper methods are used in Listing 1 to render HTML `<input>` tags. If you select view source in your browser then you see the HTML source in Listing 2. Notice that the source contains standard HTML tags.

> **IMPORTANT**
> notice that the `Html.TextBox()` -HTML Helper is rendered with `<%= %>` tags instead of `<% %>` tags. If you don't include the equal sign, then nothing gets rendered to the browser.

The ASP.NET MVC framework contains a small set of helpers. Most likely, you will need to extend the MVC framework with custom HTML Helpers. In the remainder of this tutorial, you learn two methods of creating custom HTML Helpers.

Listing 2 – `Index.aspx Source`

```
<%@ Page Language="C#" AutoEventWireup="false" CodeBehind="Index.aspx.cs" Inherits="MvcApplication1.Index" %>
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-
transitional.dtd">
<html xmlns="http://www.w3.org/1999/xhtml">

<head>
     <title>Index</title>
</head>
<body>
     <div>
          <form action="http://localhost:33102/" method="post">
               <label for="firstName">First Name:</label>

               <br />
               <input id="firstName" name="firstName" type="text" value="" />
               <br /><br />
               <label for="lastName">Last Name:</label>
               <br />
               <input id="lastName" name="lastName" type="text" value="" />
               <br /><br />

               <input id="btnRegister" name="btnRegister" type="submit" value="Register" />
          </form>
     </div>
</body>
</html>
```

Creating HTML Helpers with Static Methods

The easiest way to create a new HTML Helper is to create a static method that returns a string. Imagine, for example, that you decide to create a new HTML Helper that renders an HTML `<label>` tag. You can use the class in Listing 2 to render a `<label>` .

Listing 2 – `Helpers\LabelHelper.cs`

```
using System;
namespace MvcApplication1.Helpers
{
    public class LabelHelper
    {
        public static string Label(string target, string text)
        {
            return String.Format("<label for='{0}'>{1}</label>", target, text);
        }
    }
}
```

There is nothing special about the class in Listing 2. The `Label()` method simply returns a string.

The modified Index view in Listing 3 uses the `LabelHelper` to render HTML `<label>` tags. Notice that the view

includes an `<%@ imports %>` directive that imports the `Application1.Helpers` namespace.

Listing 2 – `Views\Home\Index2.aspx`

```
<%@ Page Language="C#" AutoEventWireup="true" CodeBehind="Index2.aspx.cs"
Inherits="MvcApplication1.Views.Home.Index2"%>
<%@ Import Namespace="MvcApplication1.Helpers" %>
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-
transitional.dtd">
<html xmlns="http://www.w3.org/1999/xhtml" >
<head id="Head1" runat="server">

     <title>Index2</title>
</head>
<body>
     <div>
          <% using (Html.BeginForm())
          { %>
               <%= LabelHelper.Label("firstName", "First Name:") %>
               <br />

               <%= Html.TextBox("firstName")%>
               <br /><br />
               <%= LabelHelper.Label("lastName", "Last Name:") %>
               <br />
               <%= Html.TextBox("lastName")%>
               <br /><br />
               <input type="submit" value="Register" />
          <% } %>

     </div>
</body>
</html>
```

Creating HTML Helpers with Extension Methods

If you want to create HTML Helpers that work just like the standard HTML Helpers included in the ASP.NET MVC framework then you need to create extension methods. Extension methods enable you to add new methods to an existing class. When creating an HTML Helper method, you add new methods to the HtmlHelper class represented by a view's Html property.

The class in Listing 3 adds an extension method to the `HtmlHelper` class named `Label()`. There are a couple of things that you should notice about this class. First, notice that the class is a static class. You must define an extension method with a static class.

Second, notice that the first parameter of the `Label()` method is preceded by the keyword `this`. The first parameter of an extension method indicates the class that the extension method extends.

Listing 3 – `Helpers\LabelExtensions.cs`

```
using System;
using System.Web.Mvc;

namespace MvcApplication1.Helpers
{
     public static class LabelExtensions
     {
          public static string Label(this HtmlHelper helper, string target, string text)
          {
               return String.Format("<label for='{0}'>{1}</label>", target, text);
          }
     }
}
```

After you create an extension method, and build your application successfully, the extension method appears in Visual Studio Intellisense like all of the other methods of a class (see Figure 2). The only difference is that extension methods appear with a special symbol next to them (an icon of a downward arrow).

Figure 02: Using the Html.Label() extension method (Click to view full-size image)

The modified Index view in Listing 4 uses the Html.Label() extension method to render all of its `<label>` tags.

Listing 4 – `Views\Home\Index3.aspx`

```
<%@ Page Language="C#" AutoEventWireup="true" CodeBehind="Index3.aspx.cs"
Inherits="MvcApplication1.Views.Home.Index3" %>

<%@ Import Namespace="MvcApplication1.Helpers" %>
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-
transitional.dtd">
<html xmlns="http://www.w3.org/1999/xhtml" >
<head id="Head1" runat="server">
     <title>Index3</title>
</head>
<body>
     <div>

          <% using (Html.BeginForm())
          { %>
               <%= Html.Label("firstName", "First Name:") %>
               <br />
               <%= Html.TextBox("firstName")%>
               <br /><br />
               <%= Html.Label("lastName", "Last Name:") %>
               <br />
               <%= Html.TextBox("lastName")%>

               <br /><br />
               <input type="submit" value="Register" />
          <% } %>
     </div>
</body>
</html>
```

Summary

In this tutorial, you learned two methods of creating custom HTML Helpers. First, you learned how to create a custom `Label()` HTML Helper by creating a static method that returns a string. Next, you learned how to create a custom `Label()` HTML Helper method by creating an extension method on the `HtmlHelper` class.

In this tutorial, I focused on building an extremely simple HTML Helper method. Realize that an HTML Helper can be as complicated as you want. You can build HTML Helpers that render rich content such as tree views, menus, or tables of database data.

Using the TagBuilder Class to Build HTML Helpers (C#)

2/20/2020 • 3 minutes to read • Edit Online

by Stephen Walther

> Stephen Walther introduces you to a useful utility class in the ASP.NET MVC framework named the TagBuilder class. You can use the TagBuilder class to easily build HTML tags.

The ASP.NET MVC framework includes a useful utility class named the TagBuilder class that you can use when building HTML helpers. The TagBuilder class, as the name of the class suggests, enables you to easily build HTML tags. In this brief tutorial, you are provided with an overview of the TagBuilder class and you learn how to use this class when building a simple HTML helper that renders HTML <img> tags.

Overview of the TagBuilder Class

The TagBuilder class is contained in the System.Web.Mvc namespace. It has five methods:

- AddCssClass() - Enables you to add a new *class=""* attribute to a tag.
- GenerateId() - Enables you to add an id attribute to a tag. This method automatically replaces periods in the id (by default, periods are replaced by underscores)
- MergeAttribute() - Enables you to add attributes to a tag. There are multiple overloads of this method.
- SetInnerText() - Enables you to set the inner text of the tag. The inner text is HTML encode automatically.
- ToString() - Enables you to render the tag. You can specify whether you want to create a normal tag, a start tag, an end tag, or a self-closing tag.

The TagBuilder class has four important properties:

- Attributes - Represents all of the attributes of the tag.
- IdAttributeDotReplacement - Represents the character used by the GenerateId() method to replace periods (the default is an underscore).
- InnerHTML - Represents the inner contents of the tag. Assigning a string to this property *does not* HTML encode the string.
- TagName - Represents the name of the tag.

These methods and properties give you all of the basic methods and properties that you need to build up an HTML tag. You don't really need to use the TagBuilder class. You could use a StringBuilder class instead. However, the TagBuilder class makes your life a little easier.

Creating an Image HTML Helper

When you create an instance of the TagBuilder class, you pass the name of the tag that you want to build to the TagBuilder constructor. Next, you can call methods like the AddCssClass and MergeAttribute() methods to modify the attributes of the tag. Finally, you call the ToString() method to render the tag.

For example, Listing 1 contains an Image HTML helper. The Image helper is implemented internally with a TagBuilder that represents an HTML <img> tag.

Listing 1 - Helpers\ImageHelper.cs

```
using System.Web.Mvc;
using System.Web.Routing;

namespace MvcApplication1.Helpers
{
    public static class ImageHelper
    {
        public static string Image(this HtmlHelper helper, string id, string url, string alternateText)
        {
            return Image(helper, id, url, alternateText, null);
        }

        public static string Image(this HtmlHelper helper, string id, string url, string alternateText, object
htmlAttributes)
        {
            // Create tag builder
            var builder = new TagBuilder("img");

            // Create valid id
            builder.GenerateId(id);

            // Add attributes
            builder.MergeAttribute("src", url);
            builder.MergeAttribute("alt", alternateText);
            builder.MergeAttributes(new RouteValueDictionary(htmlAttributes));

            // Render tag
            return builder.ToString(TagRenderMode.SelfClosing);
        }

    }
}
```

The class in Listing 1 contains two static overloaded methods named Image. When you call the Image() method, you can pass an object which represents a set of HTML attributes or not.

Notice how the TagBuilder.MergeAttribute() method is used to add individual attributes such as the src attribute to the TagBuilder. Notice, furthermore, how the TagBuilder.MergeAttributes() method is used to add a collection of attributes to the TagBuilder. The MergeAttributes() method accepts a Dictionary<string,object> parameter. The RouteValueDictionary class is used to convert the Object representing the collection of attributes into a Dictionary<string,object>.

After you create the Image helper, you can use the helper in your ASP.NET MVC views just like any of the other standard HTML helpers. The view in Listing 2 uses the Image helper to display the same image of an Xbox twice (see Figure 1). The Image() helper is called both with and without an HTML attribute collection.

Listing 2 - Home\Index.aspx

```
<%@ Page Language="C#" MasterPageFile="~/Views/Shared/Site.Master" Inherits="System.Web.Mvc.ViewPage" %>
<%@ Import Namespace="MvcApplication1.Helpers" %>

<asp:Content ID="indexContent" ContentPlaceHolderID="MainContent" runat="server">

    <!-- Calling helper without HTML attributes -->
    <%= Html.Image("img1", ResolveUrl("~/Content/XBox.jpg"), "XBox Console") %>

    <!-- Calling helper with HTML attributes -->
    <%= Html.Image("img1", ResolveUrl("~/Content/XBox.jpg"), "XBox Console", new {border="4px"})%>

</asp:Content>
```

Figure 01: Using the Image helper(Click to view full-size image)

Notice that you must import the namespace associated with the Image helper at the top of the Index.aspx view. The helper is imported with the following directive:

```
<%@ Import Namespace="MvcApplication1.Helpers" %>
```

Creating Page Layouts with View Master Pages (C#)

4/10/2020 • 7 minutes to read • Edit Online

by Microsoft

Download PDF

> In this tutorial, you learn how to create a common page layout for multiple pages in your application by taking advantage of view master pages. You can use a view master page, for example, to define a two-column page layout and use the two-column layout for all of the pages in your web application.

Creating Page Layouts with View Master Pages

In this tutorial, you learn how to create a common page layout for multiple pages in your application by taking advantage of view master pages. You can use a view master page, for example, to define a two-column page layout and use the two-column layout for all of the pages in your web application.

You also can take advantage of view master pages to share common content across multiple pages in your application. For example, you can place your website logo, navigation links, and banner advertisements in a view master page. That way, every page in your application would display this content automatically.

In this tutorial, you learn how to create a new view master page and create a new view content page based on the master page.

Creating a View Master Page

Let's start by creating a view master page that defines a two-column layout. You add a new view master page to an MVC project by right-clicking the Views\Shared folder, selecting the menu option **Add, New Item**, and selecting the **MVC View Master Page** template (see Figure 1).

Figure 01: Adding a view master page (Click to view full-size image)

You can create more than one view master page in an application. Each view master page can define a different page layout. For example, you might want certain pages to have a two-column layout and other pages to have a three-column layout.

A view master page looks very much like a standard ASP.NET MVC view. However, unlike a normal view, a view master page contains one or more `<asp:ContentPlaceHolder>` tags. The `<contentplaceholder>` tags are used to mark the areas of the master page that can be overridden in an individual content page.

For example, the view master page in Listing 1 defines a two-column layout. It contains two `<contentplaceholder>` tags. One `<ContentPlaceHolder>` for each column.

Listing 1 – `Views\Shared\Site.master`

```
<%@ Master Language="C#" AutoEventWireup="true" CodeBehind="Site.Master.cs"
Inherits="MvcApplication1.Views.Shared.Main" %>
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-
transitional.dtd">
<html xmlns="http://www.w3.org/1999/xhtml" >
<head id="Head1" runat="server">
     <title></title>

     <style type="text/css">

     html
     {
           background-color:gray;
     }

     .column
     {
          float:left;
          width:300px;
          border:solid 1px black;
          margin-right:10px;
          padding:5px;
          background-color:white;

          min-height:500px;
     }

     </style>

     <asp:ContentPlaceHolder ID="head" runat="server">
     </asp:ContentPlaceHolder>
</head>
<body>

     <h1>My Website</h1>

     <div class="column">
          <asp:ContentPlaceHolder ID="ContentPlaceHolder1" runat="server">
          </asp:ContentPlaceHolder>
     </div>
     <div class="column">
          <asp:ContentPlaceHolder ID="ContentPlaceHolder2" runat="server">
          </asp:ContentPlaceHolder>
     </div>

</body>
</html>
```

The body of the view master page in Listing 1 contains two `<div>` tags that correspond to the two columns. The Cascading Style Sheet column class is applied to both `<div>` tags. This class is defined in the style sheet declared at the top of the master page. You can preview how the view master page will be rendered by switching to Design

view. Click the Design tab at the bottom-left of the source code editor (see Figure 2).

Figure 02: Previewing a master page in the designer (Click to view full-size image)

Creating a View Content Page

After you create a view master page, you can create one or more view content pages based on the view master page. For example, you can create an Index view content page for the Home controller by right-clicking the Views\Home folder, selecting **Add, New Item**, selecting the **MVC View Content Page** template, entering the name Index.aspx, and clicking the **Add** button (see Figure 3).

Figure 03: Adding a view content page (Click to view full-size image)

After you click the Add button, a new dialog appears that enables you to select a view master page to associate

with the view content page (see Figure 4). You can navigate to the Site.master view master page that we created in the previous section.

Figure 04: Selecting a master page (Click to view full-size image)

After you create a new view content page based on the Site.master master page, you get the file in Listing 2.

Listing 2 – `Views\Home\Index.aspx`

```
<%@ Page Title="" Language="C#" MasterPageFile="~/Views/Shared/Site.Master" AutoEventWireup="true"
CodeBehind="Index.aspx.cs" Inherits="MvcApplication1.Views.Home.Index" %>

<asp:Content ID="Content1" ContentPlaceHolderID="head" runat="server">
</asp:Content>
<asp:Content ID="Content2" ContentPlaceHolderID="ContentPlaceHolder1" runat="server">
</asp:Content>
<asp:Content ID="Content3" ContentPlaceHolderID="ContentPlaceHolder2" runat="server">
</asp:Content>
```

Notice that this view contains a `<asp:Content>` tag that corresponds to each of the `<asp:ContentPlaceHolder>` tags in the view master page. Each `<asp:Content>` tag includes a ContentPlaceHolderID attribute that points to the particular `<asp:ContentPlaceHolder>` that it overrides.

Notice, furthermore, that the content view page in Listing 2 does not contain any of the normal opening and closing HTML tags. For example, it does not contain the opening and closing `<html>` or `<head>` tags. All of the normal opening and closing tags are contained in the view master page.

Any content that you want to display in a view content page must be placed within a `<asp:Content>` tag. If you place any HTML or other content outside of these tags, then you will get an error when you attempt to view the page.

You don't need to override every `<asp:ContentPlaceHolder>` tag from a master page in a content view page. You only need to override a `<asp:ContentPlaceHolder>` tag when you want to replace the tag with particular content.

For example, the modified Index view in Listing 3 contains only two `<asp:Content>` tags. Each of the `<asp:Content>` tags includes some text.

Listing 3 – `Views\Home\Index.aspx (modified)`

```
<%@ Page Title="" Language="C#" MasterPageFile="~/Views/Shared/Site.Master" AutoEventWireup="true"
CodeBehind="Index.aspx.cs" Inherits="MvcApplication1.Views.Home.Index" %>
<asp:Content ID="Content2" ContentPlaceHolderID="ContentPlaceHolder1" runat="server">

     <h1>Content in first column!</h1>

</asp:Content>
<asp:Content ID="Content3" ContentPlaceHolderID="ContentPlaceHolder2" runat="server">

     <h1>Content in second column!</h1>

</asp:Content>
```

When the view in Listing 3 is requested, it renders the page in Figure 5. Notice that the view renders a page with two columns. Notice, furthermore, that the content from the view content page is merged with the content from the view master page

Figure 05: The Index view content page (Click to view full-size image)

Modifying View Master Page Content

One issue that you encounter almost immediately when working with view master pages is the problem of modifying view master page content when different view content pages are requested. For example, you want each page in your web application to have a unique title. However, the title is declared in the view master page and not in the view content page. So, how do you customize the page title for each view content page?

There are two ways that you can modify the title displayed by a view content page. First, you can assign a page title to the title attribute of the `<%@ page %>` directive declared at the top of a view content page. For example, if you want to assign the page title "Super Great Website" to the Index view, then you can include the following directive at the top of the Index view:

```
<%@ page title="Super Great Website" language="C#" masterpagefile="~/Views/Shared/Site.Master"
            autoeventwireup="true" codebehind="Index.aspx.cs" inherits="MvcApplication1.Views.Home.Index"%>
```

When the Index view is rendered to the browser, the desired title appears in the browser title bar:

There is one important requirement that a master view page must satisfy in order for the title attribute to work. The view master page must contain a `<head runat="server">` tag instead of a normal `<head>` tag for its header. If the `<head>` tag does not include the runat="server" attribute then the title won't appear. The default view master page includes the required `<head runat="server">` tag.

An alternative approach to modifying master page content from an individual view content page is to wrap the region that you want to modify in a `<asp:ContentPlaceHolder>` tag. For example, imagine that you want to change not only the title, but also the meta tags, rendered by a master view page. The master view page in Listing 4 contains a `<asp:ContentPlaceHolder>` tag within its `<head>` tag.

Listing 4 – `Views\Shared\Site2.master`

```
<%@ Master Language="C#" AutoEventWireup="true" CodeBehind="Site2.Master.cs"
Inherits="MvcApplication1.Views.Shared.Site2" %>
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-
transitional.dtd">
<html xmlns="http://www.w3.org/1999/xhtml" >
<head>

     <asp:ContentPlaceHolder ID="head" runat="server">
          <title>Please change my title</title>
          <meta name="description" content="Please provide a description" />
          <meta name="keywords" content="keyword1,keyword2" />
     </asp:ContentPlaceHolder>
</head>
<body>
     <div>

          <asp:ContentPlaceHolder ID="ContentPlaceHolder1" runat="server">

          </asp:ContentPlaceHolder>
     </div>
</body>
</html>
```

Notice that the `<asp:ContentPlaceHolder>` tag in Listing 4 includes default content: a default title and default meta tags. If you don't override this `<asp:ContentPlaceHolder>` tag in an individual view content page, then the default content will be displayed.

The content view page in Listing 5 overrides the `<asp:ContentPlaceHolder>` tag in order to display a custom title and custom meta tags.

Listing 5 – `Views\Home\Index2.aspx`

```
<%@ Page Title="" Language="C#" MasterPageFile="~/Views/Shared/Site2.Master" AutoEventWireup="true"
CodeBehind="Index2.aspx.cs" Inherits="MvcApplication1.Views.Home.Index2" %>

<asp:Content ID="Content1" ContentPlaceHolderID="head" runat="server">
     <title>The Index2 Page</title>
     <meta name="description" content="Description of Index2 page" />
     <meta name="keywords" content="asp.net,mvc,cool,groovy" />
</asp:Content>
<asp:Content ID="Content2" ContentPlaceHolderID="ContentPlaceHolder1" runat="server">

     Just some content in the body of the page.

</asp:Content>
```

Summary

This tutorial provided you with a basic introduction to view master pages and view content pages. You learned how to create new view master pages and create view content pages based on them. We also examined how you can modify the content of a view master page from a particular view content page.

Download PDF

The goal of this tutorial is to explain how you can pass data from a controller to a view master page. We examine two strategies for passing data to a view master page. First, we discuss an easy solution that results in an application that is difficult to maintain. Next, we examine a much better solution that requires a little more initial work but results in a much more maintainable application.

Passing Data to View Master Pages

The goal of this tutorial is to explain how you can pass data from a controller to a view master page. We examine two strategies for passing data to a view master page. First, we discuss an easy solution that results in an application that is difficult to maintain. Next, we examine a much better solution that requires a little more initial work but results in a much more maintainable application.

The Problem

Imagine that you are building a movie database application and you want to display the list of movie categories on every page in your application (see Figure 1). Imagine, furthermore, that the list of movie categories is stored in a database table. In that case, it would make sense to retrieve the categories from the database and render the list of movie categories within a view master page.

Figure 01: Displaying movie categories in a view master page (Click to view full-size image)

Here's the problem. How do you retrieve the list of movie categories in the master page? It is tempting to call methods of your model classes in the master page directly. In other words, it is tempting to include the code for retrieving the data from the database right in your master page. However, bypassing your MVC controllers to access the database would violate the clean separation of concerns that is one of the primary benefits of building an MVC application.

In an MVC application, you want all interaction between your MVC views and your MVC model to be handled by your MVC controllers. This separation of concerns results in a more maintainable, adaptable, and testable application.

In an MVC application, all data passed to a view – including a view master page – should be passed to a view by a controller action. Furthermore, the data should be passed by taking advantage of view data. In the remainder of this tutorial, I examine two methods of passing view data to a view master page.

The Simple Solution

Let's start with the simplest solution to passing view data from a controller to a view master page. The simplest solution is to pass the view data for the master page in each and every controller action.

Consider the controller in Listing 1. It exposes two actions named `Index()` and `Details()`. The `Index()` action method returns every movie in the Movies database table. The `Details()` action method returns every movie in a particular movie category.

Listing 1 – `Controllers\HomeController.cs`

```
using System.Linq;
using System.Web.Mvc;
using MvcApplication1.Models;

namespace MvcApplication1.Controllers
{
     [HandleError]
     public class HomeController : Controller
     {
          private MovieDataContext _dataContext = new MovieDataContext();

          /// <summary>

          /// Show list of all movies
          /// </summary>
          public ActionResult Index()
          {
               ViewData["categories"] = from c in _dataContext.MovieCategories
                         select c;
               ViewData["movies"] = from m in _dataContext.Movies
                         select m;
               return View();
          }

          /// <summary>
          /// Show list of movies in a category
          /// </summary>

          public ActionResult Details(int id)
          {
               ViewData["categories"] = from c in _dataContext.MovieCategories
                         select c;
               ViewData["movies"] = from m in _dataContext.Movies
                         where m.CategoryId == id
                         select m;
               return View();
          }
     }
}
```

Notice that both the Index() and the Details() actions add two items to view data. The Index() action adds two keys: categories and movies. The categories key represents the list of movie categories displayed by the view master page. The movies key represents the list of movies displayed by the Index view page.

The Details() action also adds two keys named categories and movies. The categories key, once again, represents the list of movie categories displayed by the view master page. The movies key represents the list of movies in a particular category displayed by the Details view page (see Figure 2).

Figure 02: The Details view (Click to view full-size image)

The Index view is contained in Listing 2. It simply iterates through the list of movies represented by the movies item in view data.

Listing 2 – `Views\Home\Index.aspx`

```
<%@ Page Title="" Language="C#" MasterPageFile="~/Views/Shared/Site.Master" AutoEventWireup="true"
CodeBehind="Index.aspx.cs" Inherits="MvcApplication1.Views.Home.Index" %>

<%@ Import Namespace="MvcApplication1.Models" %>
<asp:Content ID="Content1" ContentPlaceHolderID="ContentPlaceHolder1" runat="server">

<ul>

<% foreach (var m in (IEnumerable<Movie>)ViewData["movies"])
     { %>

     <li><%= m.Title %></li>

<% } %>
</ul>

</asp:Content>
```

The view master page is contained in Listing 3. The view master page iterates and renders all of the movie categories represented by the categories item from view data.

Listing 3 – `Views\Shared\Site.master`

```
<%@ Master Language="C#" AutoEventWireup="true" CodeBehind="Site.Master.cs"
Inherits="MvcApplication1.Views.Shared.Site" %>
<%@ Import Namespace="MvcApplication1.Models" %>
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-
transitional.dtd">

<html xmlns="http://www.w3.org/1999/xhtml" >
<head id="Head1" runat="server">
     <title></title>
     <asp:ContentPlaceHolder ID="head" runat="server">

     </asp:ContentPlaceHolder>
</head>
<body>
     <div>
          <h1>My Movie Website</h1>

          <% foreach (var c in (IEnumerable<MovieCategory>)ViewData["categories"])
                          {%>

               <%= Html.ActionLink(c.Name, "Details", new {id=c.Id} ) %>

          <% } %>

          <asp:ContentPlaceHolder ID="ContentPlaceHolder1" runat="server">

          </asp:ContentPlaceHolder>
     </div>
</body>
</html>
```

All data is passed to the view and the view master page through view data. That is the correct way to pass data to the master page.

So, what's wrong with this solution? The problem is that this solution violates the DRY (Don't Repeat Yourself) principle. Each and every controller action must add the very same list of movie categories to view data. Having duplicate code in your application makes your application much more difficult to maintain, adapt, and modify.

The Good Solution

In this section, we examine an alternative, and better, solution to passing data from a controller action to a view master page. Instead of adding the movie categories for the master page in each and every controller action, we add the movie categories to the view data only once. All view data used by the view master page is added in an Application controller.

The ApplicationController class is contained in Listing 4.

Listing 4 – `Controllers\ApplicationController.cs`

```
using System.Linq;
using System.Web.Mvc;
using MvcApplication1.Models;

namespace MvcApplication1.Controllers
{
     public abstract class ApplicationController : Controller
     {
          private MovieDataContext _dataContext = new MovieDataContext();

          public MovieDataContext DataContext
          {
               get { return _dataContext; }
          }

          public ApplicationController()
          {
               ViewData["categories"] = from c in DataContext.MovieCategories
                         select c;
          }

     }
}
```

There are three things that you should notice about the Application controller in Listing 4. First, notice that the class inherits from the base System.Web.Mvc.Controller class. The Application controller is a controller class.

Second, notice that the Application controller class is an abstract class. An abstract class is a class that must be implemented by a concrete class. Because the Application controller is an abstract class, you cannot not invoke any methods defined in the class directly. If you attempt to invoke the Application class directly then you'll get a Resource Cannot Be Found error message.

Third, notice that the Application controller contains a constructor that adds the list of movie categories to view data. Every controller class that inherits from the Application controller calls the Application controller's constructor automatically. Whenever you call any action on any controller that inherits from the Application controller, the movie categories is included in the view data automatically.

The Movies controller in Listing 5 inherits from the Application controller.

Listing 5 – `Controllers\MoviesController.cs`

```
using System.Linq;
using System.Web.Mvc;

namespace MvcApplication1.Controllers
{
     public class MoviesController : ApplicationController
     {
          /// <summary>

          /// Show list of all movies
          /// </summary>
          public ActionResult Index()
          {
               ViewData["movies"] = from m in DataContext.Movies
                         select m;
               return View();
          }

          /// <summary>
          /// Show list of movies in a category
          /// </summary>

          public ActionResult Details(int id)
          {
               ViewData["movies"] = from m in DataContext.Movies
                         where m.CategoryId == id
                         select m;
               return View();
          }

     }
}
```

The Movies controller, just like the Home controller discussed in the previous section, exposes two action methods named `Index()` and `Details()`. Notice that the list of movie categories displayed by the view master page is not added to view data in either the `Index()` or `Details()` method. Because the Movies controller inherits from the Application controller, the list of movie categories is added to view data automatically.

Notice that this solution to adding view data for a view master page does not violate the DRY (Don't Repeat Yourself) principle. The code for adding the list of movie categories to view data is contained in only one location: the constructor for the Application controller.

Summary

In this tutorial, we discussed two approaches to passing view data from a controller to a view master page. First, we examined a simple, but difficult to maintain approach. In the first section, we discussed how you can add view data for a view master page in each every controller action in your application. We concluded that this was a bad approach because it violates the DRY (Don't Repeat Yourself) principle.

Next, we examined a much better strategy for adding data required by a view master page to view data. Instead of adding the view data in each and every controller action, we added the view data only once within an Application controller. That way, you can avoid duplicate code when passing data to a view master page in an ASP.NET MVC application.

ASP.NET MVC Views Overview (VB)

9/16/2020 • 7 minutes to read • Edit Online

by Stephen Walther

> What is an ASP.NET MVC View and how does it differ from a HTML page? In this tutorial, Stephen Walther introduces you to Views and demonstrates how you can take advantage of View Data and HTML Helpers within a View.

The purpose of this tutorial is to provide you with a brief introduction to ASP.NET MVC views, view data, and HTML Helpers. By the end of this tutorial, you should understand how to create new views, pass data from a controller to a view, and use HTML Helpers to generate content in a view.

Understanding Views

Unlike ASP.NET or Active Server Pages, ASP.NET MVC does not include anything that directly corresponds to a page. In an ASP.NET MVC application, there is not a page on disk that corresponds to the path in the URL that you type into the address bar of your browser. The closest thing to a page in an ASP.NET MVC application is something called a *view*.

In an ASP.NET MVC application, incoming browser requests are mapped to controller actions. A controller action might return a view. However, a controller action might perform some other type of action such as redirecting you to another controller action.

Listing 1 contains a simple controller named the HomeController. The HomeController exposes two controller actions named Index() and Details().

Listing 1 - HomeController.vb

```
<HandleError()> _
Public Class HomeController
    Inherits System.Web.Mvc.Controller

    Function Index()
        Return View()
    End Function

    Function Details()
        Return RedirectToAction("Index")
    End Function
End Class
```

You can invoke the first action, the Index() action, by typing the following URL into your browser address bar:

/Home/Index

You can invoke the second action, the Details() action, by typing this address into your browser:

/Home/Details

The Index() action returns a view. Most actions that you create will return views. However, an action can return other types of action results. For example, the Details() action returns a RedirectToActionResult that redirects incoming request to the Index() action.

The Index() action contains the following single line of code:

View()

This line of code returns a view that must be located at the following path on your web server:

\Views\Home\Index.aspx

The path to the view is inferred from the name of the controller and the name of the controller action.

If you prefer, you can be explicit about the view. The following line of code returns a view named Fred :

View(Fred)

When this line of code is executed, a view is returned from the following path:

\Views\Home\Fred.aspx

> **NOTE**
> If you plan to create unit tests for your ASP.NET MVC application then it is a good idea to be explicit about view names. That way, you can create a unit test to verify that the expected view was returned by a controller action.

Adding Content to a View

A view is a standard (X)HTML document that can contain scripts. You use scripts to add dynamic content to a view.

For example, the view in Listing 2 displays the current date and time.

Listing 2 - \Views\Home\Index.aspx

```
<%@ Page Language="VB" Inherits="System.Web.Mvc.ViewPage" %>

<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-
transitional.dtd">
<html xmlns="http://www.w3.org/1999/xhtml" >
<head id="Head1" runat="server">
    <title>Index</title>
</head>
<body>
    <div>

    The current date and time is
    <% Response.Write(DateTime.Now)%>

    </div>
</body>
</html>
```

Notice that the body of the HTML page in Listing 2 contains the following script:

<% Response.Write(DateTime.Now)%>

You use the script delimiters <% and %> to mark the beginning and end of a script. This script is written in Visual basic. It displays the current date and time by calling the Response.Write() method to render content to the browser. The script delimiters <% and %> can be used to execute one or more statements.

Since you call Response.Write() so often, Microsoft provides you with a shortcut for calling the Response.Write() method. The view in Listing 3 uses the delimiters <%= and %> as a shortcut for calling Response.Write().

Listing 3 - Views\Home\Index2.aspx

```
<%@ Page Language="VB" Inherits="System.Web.Mvc.ViewPage" %>

<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-
transitional.dtd">
<html xmlns="http://www.w3.org/1999/xhtml" >
<head id="Head1" runat="server">
    <title>Index</title>
</head>
<body>
    <div>

    The current date and time is
    <%= DateTime.Now %>

    </div>
</body>
</html>
```

You can use any .NET language to generate dynamic content in a view. Normally, you'll use either Visual Basic .NET or C# to write your controllers and views.

Using HTML Helpers to Generate View Content

To make it easier to add content to a view, you can take advantage of something called an *HTML Helper*. An HTML Helper, typically, is a method that generates a string. You can use HTML Helpers to generate standard HTML elements such as textboxes, links, dropdown lists, and list boxes.

For example, the view in Listing 4 takes advantage of three HTML Helpers -- the BeginForm(), the TextBox() and Password() helpers -- to generate a Login form (see Figure 1).

Listing 4 -- \Views\Home\Login.aspx

```
<%@ Page Language="VB" Inherits="System.Web.Mvc.ViewPage" %>

<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-
transitional.dtd">

<html xmlns="http://www.w3.org/1999/xhtml" >
<head id="Head1" runat="server">
    <title>Login Form</title>
</head>
<body>
    <div>

    <%  Using Html.BeginForm()%>

        <label for="UserName">User Name:</label>
        <br />
        <%= Html.TextBox("UserName") %>

        <br /><br />

        <label for="Password">Password:</label>
        <br />
        <%= Html.Password("Password") %>

        <br /><br />

        <input type="submit" value="Log in" />

    <% End Using%>

    </div>
</body>
</html>
```

Figure 01: A standard Login form (Click to view full-size image)

All of the HTML Helpers methods are called on the Html property of the view. For example, you render a TextBox by calling the Html.TextBox() method.

Notice that you use the script delimiters <%= and %> when calling both the Html.TextBox() and Html.Password() helpers. These helpers simply return a string. You need to call Response.Write() in order to render the string to the browser.

Using HTML Helper methods is optional. They make your life easier by reducing the amount of HTML and script that you need to write. The view in Listing 5 renders the exact same form as the view in Listing 4 without using HTML Helpers.

Listing 5 -- \Views\Home\Login.aspx

```
<%@ Page Language="VB" Inherits="System.Web.Mvc.ViewPage" %>

<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-
transitional.dtd">

<html xmlns="http://www.w3.org/1999/xhtml" >
<head id="Head1" runat="server">
    <title>Login Form</title>
</head>
<body>
    <div>

    <form method="post" action="/Home/Login">

    <label for="userName">User Name:</label>
    <br />
    <input name="userName" />

    <br /><br />

    <label for="password">Password:</label>
    <br />
    <input name="password" type="password" />

    <br /><br />
    <input type="submit" value="Log In" />

    </form>

    </div>
</body>
</html>
```

You also have the option of creating your own HTML Helpers. For example, you can create a GridView() helper method that displays a set of database records in an HTML table automatically. We explore this topic in the tutorial **Creating Custom HTML Helpers**.

Using View Data to Pass Data to a View

You use view data to pass data from a controller to a view. Think of view data like a package that you send through the mail. All data passed from a controller to a view must be sent using this package. For example, the controller in Listing 6 adds a message to view data.

Listing 6 - ProductController.vb

```
Public Class ProductController
    Inherits System.Web.Mvc.Controller

    Function Index()
        ViewData("message") = "Hello World!"
        Return View()
    End Function

End Class
```

The controller ViewData property represents a collection of name and value pairs. In Listing 6, the Index() method adds an item to the view data collection named message with the value Hello World!. When the view is returned by the Index() method, the view data is passed to the view automatically.

The view in Listing 7 retrieves the message from the view data and renders the message to the browser.

Listing 7 -- \Views\Product\Index.aspx

```
<%@ Page Language="VB" Inherits="System.Web.Mvc.ViewPage" %>

<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-
transitional.dtd">
<html xmlns="http://www.w3.org/1999/xhtml" >
<head id="Head1" runat="server">
    <title>Product Index</title>
</head>
<body>
    <div>

    <%=Html.Encode(ViewData("message"))%>

    </div>
</body>
</html>
```

Notice that the view takes advantage of the Html.Encode() HTML Helper method when rendering the message. The Html.Encode() HTML Helper encodes special characters such as < and > into characters that are safe to display in a web page. Whenever you render content that a user submits to a website, you should encode the content to prevent JavaScript injection attacks.

(Because we created the message ourselves in the ProductController, we don't really need to encode the message. However, it is a good habit to always call the Html.Encode() method when displaying content retrieved from view data within a view.)

In Listing 7, we took advantage of view data to pass a simple string message from a controller to a view. You also can use view data to pass other types of data, such as a collection of database records, from a controller to a view. For example, if you want to display the contents of the Products database table in a view, then you would pass the collection of database records in view data.

You also have the option of passing strongly typed view data from a controller to a view. We explore this topic in the tutorial **Understanding Strongly Typed View Data and Views**.

Summary

This tutorial provided a brief introduction to ASP.NET MVC views, view data, and HTML Helpers. In the first section, you learned how to add new views to your project. You learned that you must add a view to the right folder in order to call it from a particular controller. Next, we discussed the topic of HTML Helpers. You learned how HTML Helpers enable you to easily generate standard HTML content. Finally, you learned how to take advantage of view data to pass data from a controller to a view.

> The goal of this tutorial is to demonstrate how you can create custom HTML Helpers that you can use within your MVC views. By taking advantage of HTML Helpers, you can reduce the amount of tedious typing of HTML tags that you must perform to create a standard HTML page.

The goal of this tutorial is to demonstrate how you can create custom HTML Helpers that you can use within your MVC views. By taking advantage of HTML Helpers, you can reduce the amount of tedious typing of HTML tags that you must perform to create a standard HTML page.

In the first part of this tutorial, I describe some of the existing HTML Helpers included with the ASP.NET MVC framework. Next, I describe two methods of creating custom HTML Helpers: I explain how to create custom HTML Helpers by creating a shared method and by creating an extension method.

Understanding HTML Helpers

An HTML Helper is just a method that returns a string. The string can represent any type of content that you want. For example, you can use HTML Helpers to render standard HTML tags like HTML `<input>` and `<img>` tags. You also can use HTML Helpers to render more complex content such as a tab strip or an HTML table of database data.

The ASP.NET MVC framework includes the following set of standard HTML Helpers (this is not a complete list):

- Html.ActionLink()
- Html.BeginForm()
- Html.CheckBox()
- Html.DropDownList()
- Html.EndForm()
- Html.Hidden()
- Html.ListBox()
- Html.Password()
- Html.RadioButton()
- Html.TextArea()
- Html.TextBox()

For example, consider the form in Listing 1. This form is rendered with the help of two of the standard HTML Helpers (see Figure 1). This form uses the `Html.BeginForm()` and `Html.TextBox()` Helper methods.

Figure 01: Page rendered with HTML Helpers (Click to view full-size image)

Listing 1 – `Views\Home\Index.aspx`

```
<%@ Page Language="VB" AutoEventWireup="false" CodeBehind="Index.aspx.vb" Inherits="MvcApplication1.Index"%>
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-
transitional.dtd">

<html xmlns= "http://www.w3.org/1999/xhtml ">
<head id="Head1" runat="server">
     <title>Index</title>
</head>
<body>
      <div>
     <% Using Html.BeginForm()
          <label for="firstName">First Name:</label>

          <br />
          <%= Html.TextBox("firstName")%>
          <br /><br />
          <label for="lastName">Last Name:</label>
          <br />
          <%= Html.TextBox("lastName")%>
          <br /><br />

          <input type="submit" value="Register" />
     <% End Using %>
     </div>
</body>
</html>
```

The `Html.BeginForm()` Helper method is used to create the opening and closing HTML `<form>` tags. Notice that the `Html.BeginForm()` method is called within a using statement. The using statement ensures that the `<form>` tag gets closed at the end of the using block.

If you prefer, instead of creating a using block, you can call the Html.EndForm() Helper method to close the `<form>` tag. Use whichever approach to creating an opening and closing `<form>` tag that seems most intuitive to you.

The `Html.TextBox()` Helper methods are used in Listing 1 to render HTML `<input>` tags. If you select view source in your browser then you see the HTML source in Listing 2. Notice that the source contains standard HTML tags.

> **IMPORTANT**
> notice that the `Html.TextBox()` -HTML Helper is rendered with `<%= %>` tags instead of `<% %>` tags. If you don't include the equal sign, then nothing gets rendered to the browser.

The ASP.NET MVC framework contains a small set of helpers. Most likely, you will need to extend the MVC framework with custom HTML Helpers. In the remainder of this tutorial, you learn two methods of creating custom HTML Helpers.

Listing 2 – `Index.aspx Source`

```
<%@ Page Language="VB" AutoEventWireup="false" CodeBehind="Index.aspx.vb" Inherits="MvcApplication1.Index" %>

<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-
transitional.dtd">
<html xmlns="http://www.w3.org/1999/xhtml">
<head>
     <title>Index</title>
</head>
<body>
     <div>
     <form action="http://localhost:33102/" method="post">

          <label for="firstName">First Name:</label>
          <br />
          <input id="firstName" name="firstName" type="text" value="" />
          <br /><br />
          <label for="lastName">Last Name:</label>
          <br />

          <input id="lastName" name="lastName" type="text" value="" />
          <br /><br />
          <input id="btnRegister" name="btnRegister" type="submit" value="Register" />
     </form>
     </div>
</body>
</html>
```

Creating HTML Helpers with Shared Methods

The easiest way to create a new HTML Helper is to create a shared method that returns a string. Imagine, for example, that you decide to create a new HTML Helper that renders an HTML `<label>` tag. You can use the class in Listing 2 to render a `<label>`.

Listing 2 – `Helpers\LabelHelper.vb`

```
Public Class LabelHelper
Public Shared Function Label(ByVal target As String, ByVal text As String) As String
     Return String.Format("<label for='{0}'>{1}</label>", target, text)
End Function
End Class
```

There is nothing special about the class in Listing 2. The `Label()` method simply returns a string.

The modified Index view in Listing 3 uses the `LabelHelper` to render HTML `<label>` tags. Notice that the view includes an `<%@ imports %>` directive that imports the Application1.Helpers namespace.

Listing 2 – `Views\Home\Index2.aspx`

```
<%@ Page Language="VB" AutoEventWireup="false" CodeBehind="Index2.aspx.vb" Inherits="MvcApplication1.Index2"%>
<%@ Import Namespace="MvcApplication1" %>
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-
transitional.dtd">
<html xmlns="http://www.w3.org/1999/xhtml" >
<head id="Head1" runat="server">
     <title>Index2</title>
</head>

<body>
     <div>
     <% Using Html.BeginForm()
          <%= LabelHelper.Label("firstName", "First Name:") %>
          <br />
          <%= Html.TextBox("firstName") %>
          <br /><br />
          <%= LabelHelper.Label("lastName", "Last Name:") %>
          <br />

          <%= Html.TextBox("lastName") %>
          <br /><br />
          <input type="submit" value="Register" />
     <% End Using %>
     </div>
</body>
</html>
```

Creating HTML Helpers with Extension Methods

If you want to create HTML Helpers that work just like the standard HTML Helpers included in the ASP.NET MVC framework then you need to create extension methods. Extension methods enable you to add new methods to an existing class. When creating an HTML Helper method, you add new methods to the `HtmlHelper` class represented by a view's Html property.

The Visual Basic module in Listing 3 adds an extension method named `Label()` to the `HtmlHelper` class. There are a couple of things that you should notice about this module. First, notice that the module is decorated with the `<Extension()>` attribute. In order to use this attribute, you must import the `System.Runtime.CompilerServices` namespace

Second, notice that the first parameter of the `Label()` method represents the `HtmlHelper` class. The first parameter of an extension method indicates the class that the extension method extends.

Listing 3 – `Helpers\LabelExtensions.vb`

```
Imports System.Runtime.CompilerServices

Public Module LabelExtensions
     <Extension()> _
     Public Function Label(ByVal helper As HtmlHelper, ByVal target As String, ByVal text As String) As String
          Return String.Format("<label for='{0}'> {1}</label>", target, text)

     End Function
End Module
```

After you create an extension method, and build your application successfully, the extension method appears in Visual Studio Intellisense like all of the other methods of a class (see Figure 2). The only difference is that extension methods appear with a special symbol next to them (an icon of a downward arrow).

Figure 02: Using the Html.Label() extension method (Click to view full-size image)

The modified Index view in Listing 4 uses the Html.Label() extension method to render all of its <label> tags.

Listing 4 – `Views\Home\Index3.aspx`

```
<%@ Page Language="VB" AutoEventWireup="false" CodeBehind="Index3.aspx.vb" Inherits="MvcApplication1.Index3"
%>

<%@ Import Namespace="MvcApplication1" %>
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-
transitional.dtd">
<html xmlns="http://www.w3.org/1999/xhtml" >
<head id="Head1" runat="server">
     <title>Index3</title>
</head>
<body>
     <div>

     <% Using Html.BeginForm()%>
     <%=Html.Label("firstName", "First Name:")%>
     <br />
     <%= Html.TextBox("firstName")%>
     <br /><br />
     <%=Html.Label("lastName", "Last Name:")%>
     <br />
     <%= Html.TextBox("lastName")%>

     <br /><br />
     <input type="submit" value="Register" />
     <% End Using%>
     </div>
</body>
</html>
```

Summary

In this tutorial, you learned two methods of creating custom HTML Helpers. First, you learned how to create a custom `Label()` HTML Helper by creating a shared method that returns a string. Next, you learned how to create a custom `Label()` HTML Helper method by creating an extension method on the `HtmlHelper` class.

In this tutorial, I focused on building an extremely simple HTML Helper method. Realize that an HTML Helper can be as complicated as you want. You can build HTML Helpers that render rich content such as tree views, menus, or

tables of database data.

Using the TagBuilder Class to Build HTML Helpers (VB)

2/20/2020 • 3 minutes to read • Edit Online

by Stephen Walther

> Stephen Walther introduces you to a useful utility class in the ASP.NET MVC framework named the TagBuilder class. You can use the TagBuilder class to easily build HTML tags.

The ASP.NET MVC framework includes a useful utility class named the TagBuilder class that you can use when building HTML helpers. The TagBuilder class, as the name of the class suggests, enables you to easily build HTML tags. In this brief tutorial, you are provided with an overview of the TagBuilder class and you learn how to use this class when building a simple HTML helper that renders HTML <img> tags.

Overview of the TagBuilder Class

The TagBuilder class is contained in the System.Web.Mvc namespace. It has five methods:

- AddCssClass() – Enables you to add a new *class=""* attribute to a tag.
- GenerateId() – Enables you to add an id attribute to a tag. This method automatically replaces periods in the id (by default, periods are replaced by underscores)
- MergeAttribute() – Enables you to add attributes to a tag. There are multiple overloads of this method.
- SetInnerText() – Enables you to set the inner text of the tag. The inner text is HTML encode automatically.
- ToString() – Enables you to render the tag. You can specify whether you want to create a normal tag, a start tag, an end tag, or a self-closing tag.

The TagBuilder class has four important properties:

- Attributes – Represents all of the attributes of the tag.
- IdAttributeDotReplacement – Represents the character used by the GenerateId() method to replace periods (the default is an underscore).
- InnerHTML – Represents the inner contents of the tag. Assigning a string to this property *does not* HTML encode the string.
- TagName – Represents the name of the tag.

These methods and properties give you all of the basic methods and properties that you need to build up an HTML tag. You don't really need to use the TagBuilder class. You could use a StringBuilder class instead. However, the TagBuilder class makes your life a little easier.

Creating an Image HTML Helper

When you create an instance of the TagBuilder class, you pass the name of the tag that you want to build to the TagBuilder constructor. Next, you can call methods like the AddCssClass and MergeAttribute() methods to modify the attributes of the tag. Finally, you call the ToString() method to render the tag.

For example, Listing 1 contains an Image HTML helper. The Image helper is implemented internally with a TagBuilder that represents an HTML <img> tag.

Listing 1 – Helpers\ImageHelper.vb

```
Public Module ImageHelper

<System.Runtime.CompilerServices.Extension> _
Function Image(ByVal helper As HtmlHelper, ByVal id As String, ByVal url As String, ByVal alternateText As
String) As String
    Return Image(helper, id, url, alternateText, Nothing)
End Function

<System.Runtime.CompilerServices.Extension> _
Function Image(ByVal helper As HtmlHelper, ByVal id As String, ByVal url As String, ByVal alternateText As
String, ByVal htmlAttributes As Object) As String
    ' Create tag builder
    Dim builder = New TagBuilder("img")

    ' Create valid id
    builder.GenerateId(id)

    ' Add attributes
    builder.MergeAttribute("src", url)
    builder.MergeAttribute("alt", alternateText)
    builder.MergeAttributes(New RouteValueDictionary(htmlAttributes))

    ' Render tag
    Return builder.ToString(TagRenderMode.SelfClosing)
End Function

End Module
```

The module in Listing 1 contains two overloaded methods named Image(). When you call the Image() method, you can pass an object which represents a set of HTML attributes or not.

Notice how the TagBuilder.MergeAttribute() method is used to add individual attributes such as the src attribute to the TagBuilder. Notice, furthermore, how the TagBuilder.MergeAttributes() method is used to add a collection of attributes to the TagBuilder. The MergeAttributes() method accepts a Dictionary<string,object> parameter. The RouteValueDictionary class is used to convert the Object representing the collection of attributes into a Dictionary<string,object>.

After you create the Image helper, you can use the helper in your ASP.NET MVC views just like any of the other standard HTML helpers. The view in Listing 2 uses the Image helper to display the same image of an Xbox twice (see Figure 1). The Image() helper is called both with and without an HTML attribute collection.

Listing 2 – Home\Index.aspx

```
<%@ Page Language="VB" MasterPageFile="~/Views/Shared/Site.Master" Inherits="System.Web.Mvc.ViewPage" %>
<%@ Import Namespace="MvcApplication1" %>
<asp:Content ID="indexContent" ContentPlaceHolderID="MainContent" runat="server">

    <!-- Calling helper without HTML attributes -->
    <%= Html.Image("img1", ResolveUrl("~/Content/XBox.jpg"), "XBox Console") %>

    <!-- Calling helper with HTML attributes -->
    <%= Html.Image("img1", ResolveUrl("~/Content/XBox.jpg"), "XBox Console", New With {.border="4px"})%>

</asp:Content>
```

Figure 01: Using the Image helper(Click to view full-size image)

Notice that you must import the namespace associated with the Image helper at the top of the Index.aspx view. The helper is imported with the following directive:

```
<%@ Import Namespace="MvcApplication1" %>
```

In a Visual Basic application, the default namespace is the same as the name of the application.

Creating Page Layouts with View Master Pages (VB)

4/10/2020 • 7 minutes to read • Edit Online

by Microsoft

Download PDF

> In this tutorial, you learn how to create a common page layout for multiple pages in your application by taking advantage of view master pages. You can use a view master page, for example, to define a two-column page layout and use the two-column layout for all of the pages in your web application.

Creating Page Layouts with View Master Pages

In this tutorial, you learn how to create a common page layout for multiple pages in your application by taking advantage of view master pages. You can use a view master page, for example, to define a two-column page layout and use the two-column layout for all of the pages in your web application.

You also can take advantage of view master pages to share common content across multiple pages in your application. For example, you can place your website logo, navigation links, and banner advertisements in a view master page. That way, every page in your application would display this content automatically.

In this tutorial, you learn how to create a new view master page and create a new view content page based on the master page.

Creating a View Master Page

Let's start by creating a view master page that defines a two-column layout. You add a new view master page to an MVC project by right-clicking the Views\Shared folder, selecting the menu option **Add, New Item**, and selecting the MVC View Master Page template (see Figure 1).

Figure 01: Adding a view master page (Click to view full-size image)

You can create more than one view master page in an application. Each view master page can define a different page layout. For example, you might want certain pages to have a two-column layout and other pages to have a three-column layout.

A view master page looks very much like a standard ASP.NET MVC view. However, unlike a normal view, a view master page contains one or more `<asp:ContentPlaceHolder>` tags. The `<contentplaceholder>` tags are used to mark the areas of the master page that can be overridden in an individual content page.

For example, the view master page in Listing 1 defines a two-column layout. It contains two `<contentplaceholder>` tags. One `<ContentPlaceHolder>` for each column.

Listing 1 – `Views\Shared\Site.master`

```
<%@ Master Language="VB" AutoEventWireup="false" CodeBehind="Site.Master.vb" Inherits="MvcApplication1.Site"
%>

<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-
transitional.dtd">
<html xmlns="http://www.w3.org/1999/xhtml" >
<head id="Head1" runat="server">
     <title></title>

     <style type="text/css">

     html
     {
           background-color:gray;

     }

     .column
     {
          float:left;
          width:300px;
          border:solid 1px black;
          margin-right:10px;
          padding:5px;
          background-color:white;
          min-height:500px;
     }

     </style>

     <asp:ContentPlaceHolder ID="head" runat="server">
     </asp:ContentPlaceHolder>

</head>
<body>

     <h1>My Website</h1>

     <div class="column">
          <asp:ContentPlaceHolder ID="ContentPlaceHolder1" runat="server">
          </asp:ContentPlaceHolder>
     </div>

     <div class="column">
          <asp:ContentPlaceHolder ID="ContentPlaceHolder2" runat="server">
          </asp:ContentPlaceHolder>
     </div>

</body>
</html>
```

The body of the view master page in Listing 1 contains two `<div>` tags that correspond to the two columns. The Cascading Style Sheet column class is applied to both `<div>` tags. This class is defined in the style sheet declared at the top of the master page. You can preview how the view master page will be rendered by switching to Design view. Click the Design tab at the bottom-left of the source code editor (see Figure 2).

Figure 02: Previewing a master page in the designer (Click to view full-size image)

Creating a View Content Page

After you create a view master page, you can create one or more view content pages based on the view master page. For example, you can create an Index view content page for the Home controller by right-clicking the Views\Home folder, selecting **Add, New Item**, selecting the **MVC View Content Page** template, entering the name Index.aspx, and clicking the Add button (see Figure 3).

Figure 03: Adding a view content page (Click to view full-size image)

After you click the Add button, a new dialog appears that enables you to select a view master page to associate with the view content page (see Figure 4). You can navigate to the Site.master view master page that we created in the previous section.

Figure 04: Selecting a master page (Click to view full-size image)

After you create a new view content page based on the Site.master master page, you get the file in Listing 2.

Listing 2 – `Views\Home\Index.aspx`

```
<%@ Page Title="" Language="VB" MasterPageFile="~/Views/Shared/Site.Master" AutoEventWireup="false"
CodeBehind="Index.aspx.vb" Inherits="MvcApplication1.Index" %>

<asp:Content ID="Content1" ContentPlaceHolderID="head" runat="server">
</asp:Content>
<asp:Content ID="Content2" ContentPlaceHolderID="ContentPlaceHolder1" runat="server">
</asp:Content>
<asp:Content ID="Content3" ContentPlaceHolderID="ContentPlaceHolder2" runat="server">
</asp:Content>
```

Notice that this view contains a `<asp:Content>` tag that corresponds to each of the `<asp:ContentPlaceHolder>` tags in the view master page. Each `<asp:Content>` tag includes a ContentPlaceHolderID attribute that points to the particular `<asp:ContentPlaceHolder>` that it overrides.

Notice, furthermore, that the content view page in Listing 2 does not contain any of the normal opening and closing HTML tags. For example, it does not contain the opening and closing `<html>` or `<head>` tags. All of the normal opening and closing tags are contained in the view master page.

Any content that you want to display in a view content page must be placed within a `<asp:Content>` tag. If you place any HTML or other content outside of these tags, then you will get an error when you attempt to view the page.

You don't need to override every `<asp:ContentPlaceHolder>` tag from a master page in a content view page. You only need to override a `<asp:ContentPlaceHolder>` tag when you want to replace the tag with particular content.

For example, the modified Index view in Listing 3 contains only two `<asp:Content>` tags. Each of the `<asp:Content>` tags includes some text.

Listing 3 – `Views\Home\Index.aspx (modified)`

```
<%@ Page Title="" Language="VB" MasterPageFile="~/Views/Shared/Site.Master" AutoEventWireup="false"
CodeBehind="Index.aspx.vb" Inherits="MvcApplication1.Index" %>
<asp:Content ID="Content2" ContentPlaceHolderID="ContentPlaceHolder1" runat="server">

     <h1>Content in first column!</h1>

</asp:Content>
<asp:Content ID="Content3" ContentPlaceHolderID="ContentPlaceHolder2" runat="server">

     <h1>Content in second column!</h1>

</asp:Content>
```

When the view in Listing 3 is requested, it renders the page in Figure 5. Notice that the view renders a page with two columns. Notice, furthermore, that the content from the view content page is merged with the content from the view master page.

Figure 05: The Index view content page (Click to view full-size image)

Modifying View Master Page Content

One issue that you encounter almost immediately when working with view master pages is the problem of modifying view master page content when different view content pages are requested. For example, you want each page in your web application to have a unique title. However, the title is declared in the view master page and not in the view content page. So, how do you customize the page title for each view content page?

There are two ways that you can modify the title displayed by a view content page. First, you can assign a page title to the title attribute of the `<%@ page %>` directive declared at the top of a view content page. For example, if you want to assign the page title "Super Great Website" to the Index view, then you can include the following directive at the top of the Index view:

```
<%@ page title="Super Great Website" language="VB" masterpagefile="~/Views/Shared/Site.Master"
            autoeventwireup="true" codebehind="Index.aspx.vb" inherits="MvcApplication1.Views.Home.Index"%>
```

When the Index view is rendered to the browser, the desired title appears in the browser title bar:

There is one important requirement that a master view page must satisfy in order for the title attribute to work. The view master page must contain a `<head runat="server">` tag instead of a normal `<head>` tag for its header. If the `<head>` tag does not include the runat="server" attribute then the title won't appear. The default view master page includes the required `<head runat="server">` tag.

An alternative approach to modifying master page content from an individual view content page is to wrap the region that you want to modify in a `<asp:ContentPlaceHolder>` tag. For example, imagine that you want to change not only the title, but also the meta tags, rendered by a master view page. The master view page in Listing 4 contains a `<asp:ContentPlaceHolder>` tag within its `<head>` tag.

Listing 4 – `Views\Shared\Site2.master`

```
<%@ Master Language="VB" AutoEventWireup="false" CodeBehind="Site2.Master.vb" Inherits="MvcApplication1.Site2"
%>
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-
transitional.dtd">
<html xmlns="http://www.w3.org/1999/xhtml" >
<head>

     <asp:ContentPlaceHolder ID="head" runat="server">
          <title>Please change my title</title>
          <meta name="description" content="Please provide a description" />
          <meta name="keywords" content="keyword1,keyword2" />
     </asp:ContentPlaceHolder>
</head>
<body>
     <div>

          <asp:ContentPlaceHolder ID="ContentPlaceHolder1" runat="server">

          </asp:ContentPlaceHolder>
     </div>
</body>
</html>
```

Notice that the `<asp:ContentPlaceHolder>` tag in Listing 4 includes default content: a default title and default meta tags. If you don't override this `<asp:ContentPlaceHolder>` tag in an individual view content page, then the default content will be displayed.

The content view page in Listing 5 overrides the `<asp:ContentPlaceHolder>` tag in order to display a custom title and custom meta tags.

Listing 5 – `Views\Home\Index2.aspx`

```
<%@ Page Title="" Language="VB" MasterPageFile="~/Views/Shared/Site2.Master" AutoEventWireup="false"
CodeBehind="Index2.aspx.vb" Inherits="MvcApplication1.Index2" %>

<asp:Content ID="Content1" ContentPlaceHolderID="head" runat="server">
     <title>The Index2 Page</title>
     <meta name="description" content="Description of Index2 page" />
     <meta name="keywords" content="asp.net,mvc,cool,groovy" />
</asp:Content>
<asp:Content ID="Content2" ContentPlaceHolderID="ContentPlaceHolder1" runat="server">

     Just some content in the body of the page.

</asp:Content>
```

Summary

This tutorial provided you with a basic introduction to view master pages and view content pages. You learned how to create new view master pages and create view content pages based on them. We also examined how you can modify the content of a view master page from a particular view content page.

Passing Data to View Master Pages (VB)

4/10/2020 • 7 minutes to read • Edit Online

by Microsoft

Download PDF

The goal of this tutorial is to explain how you can pass data from a controller to a view master page. We examine two strategies for passing data to a view master page. First, we discuss an easy solution that results in an application that is difficult to maintain. Next, we examine a much better solution that requires a little more initial work but results in a much more maintainable application.

Passing Data to View Master Pages

The goal of this tutorial is to explain how you can pass data from a controller to a view master page. We examine two strategies for passing data to a view master page. First, we discuss an easy solution that results in an application that is difficult to maintain. Next, we examine a much better solution that requires a little more initial work but results in a much more maintainable application.

The Problem

Imagine that you are building a movie database application and you want to display the list of movie categories on every page in your application (see Figure 1). Imagine, furthermore, that the list of movie categories is stored in a database table. In that case, it would make sense to retrieve the categories from the database and render the list of movie categories within a view master page.

Figure 01: Displaying movie categories in a view master page (Click to view full-size image)

Here's the problem. How do you retrieve the list of movie categories in the master page? It is tempting to call methods of your model classes in the master page directly. In other words, it is tempting to include the code for retrieving the data from the database right in your master page. However, bypassing your MVC controllers to access the database would violate the clean separation of concerns that is one of the primary benefits of building an MVC application.

In an MVC application, you want all interaction between your MVC views and your MVC model to be handled by your MVC controllers. This separation of concerns results in a more maintainable, adaptable, and testable application.

In an MVC application, all data passed to a view – including a view master page – should be passed to a view by a controller action. Furthermore, the data should be passed by taking advantage of view data. In the remainder of this tutorial, I examine two methods of passing view data to a view master page.

The Simple Solution

Let's start with the simplest solution to passing view data from a controller to a view master page. The simplest solution is to pass the view data for the master page in each and every controller action.

Consider the controller in Listing 1. It exposes two actions named `Index()` and `Details()`. The `Index()` action method returns every movie in the Movies database table. The `Details()` action method returns every movie in a particular movie category.

Listing 1 – `Controllers\HomeController.vb`

```
<HandleError()> _
Public Class HomeController
     Inherits System.Web.Mvc.Controller

     Private _dataContext As New MovieDataContext()

     ''' <summary>

     ''' Show list of all movies
     ''' </summary>
     Function Index()
          ViewData("categories") = From c In _dataContext.MovieCategories _
                    Select c
          ViewData("movies") = From m In _dataContext.Movies _
                    Select m
          Return View()
     End Function

     ''' <summary>
     ''' Show list of movies in a category
     ''' </summary>

     Function Details(ByVal id As Integer)
          ViewData("categories") = From c In _dataContext.MovieCategories _
                    Select c
          ViewData("movies") = From m In _dataContext.Movies _
                    Where m.CategoryId = id _
                    Select m
          Return View()
     End Function

End Class
```

Notice that both the `Index()` and the `Details()` actions add two items to view data. The `Index()` action adds two keys: categories and movies. The categories key represents the list of movie categories displayed by the view master page. The movies key represents the list of movies displayed by the Index view page.

The `Details()` action also adds two keys named categories and movies. The categories key, once again, represents the list of movie categories displayed by the view master page. The movies key represents the list of movies in a particular category displayed by the Details view page (see Figure 2).

Figure 02: The Details view (Click to view full-size image)

The Index view is contained in Listing 2. It simply iterates through the list of movies represented by the movies item in view data.

Listing 2 – `Views\Home\Index.aspx`

```
<%@ Page Title="" Language="VB" MasterPageFile="~/Views/Shared/Site.Master" AutoEventWireup="false"
CodeBehind="Index.aspx.vb" Inherits="MvcApplication1.Index" %>

<%@ Import Namespace="MvcApplication1" %>
<asp:Content ID="Content1" ContentPlaceHolderID="ContentPlaceHolder1" runat="server">

<ul>

<%  For Each m In ViewData("movies")%>

     <li><%= m.Title %></li>

<% Next%>
</ul>

</asp:Content>
```

The view master page is contained in Listing 3. The view master page iterates and renders all of the movie categories represented by the categories item from view data.

Listing 3 – `Views\Shared\Site.master`

```
<%@ Master Language="VB" AutoEventWireup="false" CodeBehind="Site.Master.vb" Inherits="MvcApplication1.Site"
%>

<%@ Import Namespace="MvcApplication1" %>
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-
transitional.dtd">

<html xmlns="http://www.w3.org/1999/xhtml" >
<head id="Head1" runat="server">

     <title></title>
     <asp:ContentPlaceHolder ID="head" runat="server">
     </asp:ContentPlaceHolder>
</head>
<body>
     <div>

          <h1>My Movie Website</h1>

          <% For Each c In ViewData("categories")%>

               <%=Html.ActionLink(c.Name, "Details", New With {.id = c.Id})%>

          <% Next%>

          <asp:ContentPlaceHolder ID="ContentPlaceHolder1" runat="server">

          </asp:ContentPlaceHolder>
     </div>
</body>
</html>
```

All data is passed to the view and the view master page through view data. That is the correct way to pass data to the master page.

So, what's wrong with this solution? The problem is that this solution violates the DRY (Don't Repeat Yourself) principle. Each and every controller action must add the very same list of movie categories to view data. Having duplicate code in your application makes your application much more difficult to maintain, adapt, and modify.

The Good Solution

In this section, we examine an alternative, and better, solution to passing data from a controller action to a view master page. Instead of adding the movie categories for the master page in each and every controller action, we add the movie categories to the view data only once. All view data used by the view master page is added in an Application controller.

The ApplicationController class is contained in Listing 4.

The ApplicationController class is contained in Listing 4.

Listing 4 – `Controllers\ApplicationController.vb`

```
Public MustInherit Class ApplicationController
     Inherits System.Web.Mvc.Controller

     Private _dataContext As New MovieDataContext()

     Public ReadOnly Property DataContext() As MovieDataContext
          Get

               Return _dataContext
          End Get
     End Property

     Sub New()
          ViewData("categories") = From c In DataContext.MovieCategories _
                    Select c
     End Sub

End Class
```

There are three things that you should notice about the Application controller in Listing 4. First, notice that the class inherits from the base System.Web.Mvc.Controller class. The Application controller is a controller class.

Second, notice that the Application controller class is a MustInherit class. An MustInherit class is a class that must be implemented by a concrete class. Because the Application controller is an MustInherit class, you cannot not invoke any methods defined in the class directly. If you attempt to invoke the Application class directly then you'll get a Resource Cannot Be Found error message.

Third, notice that the Application controller contains a constructor that adds the list of movie categories to view data. Every controller class that inherits from the Application controller calls the Application controller's constructor automatically. Whenever you call any action on any controller that inherits from the Application controller, the movie categories is included in the view data automatically.

The Movies controller in Listing 5 inherits from the Application controller.

Listing 5 – `Controllers\MoviesController.vb`

```
<HandleError()> _
Public Class MoviesController
     Inherits ApplicationController

     ''' <summary>
     ''' Show list of all movies
     ''' </summary>
     Function Index()
          ViewData("movies") = From m In DataContext.Movies _
                    Select m
          Return View()

      End Function

     ''' <summary>
     ''' Show list of movies in a category
     ''' </summary>
     Function Details(ByVal id As Integer)
          ViewData("movies") = From m In DataContext.Movies _
                    Where m.CategoryId = id _
                    Select m
          Return View()
     End Function

End Class
```

The Movies controller, just like the Home controller discussed in the previous section, exposes two action methods named `Index()` and `Details()`. Notice that the list of movie categories displayed by the view master page is not added to view data in either the `Index()` or `Details()` method. Because the Movies controller inherits from the Application controller, the list of movie categories is added to view data automatically.

Notice that this solution to adding view data for a view master page does not violate the DRY (Don't Repeat Yourself) principle. The code for adding the list of movie categories to view data is contained in only one location: the constructor for the Application controller.

Summary

In this tutorial, we discussed two approaches to passing view data from a controller to a view master page. First, we examined a simple, but difficult to maintain approach. In the first section, we discussed how you can add view data for a view master page in each every controller action in your application. We concluded that this was a bad approach because it violates the DRY (Don't Repeat Yourself) principle.

Next, we examined a much better strategy for adding data required by a view master page to view data. Instead of adding the view data in each and every controller action, we added the view data only once within an Application controller. That way, you can avoid duplicate code when passing data to a view master page in an ASP.NET MVC application.

ASP.NET MVC Routing Overview (C#)

2/20/2020 • 4 minutes to read • Edit Online

by Stephen Walther

> In this tutorial, Stephen Walther shows how the ASP.NET MVC framework maps browser requests to controller actions.

In this tutorial, you are introduced to an important feature of every ASP.NET MVC application called *ASP.NET Routing*. The ASP.NET Routing module is responsible for mapping incoming browser requests to particular MVC controller actions. By the end of this tutorial, you will understand how the standard route table maps requests to controller actions.

Using the Default Route Table

When you create a new ASP.NET MVC application, the application is already configured to use ASP.NET Routing. ASP.NET Routing is setup in two places.

First, ASP.NET Routing is enabled in your application's Web configuration file (Web.config file). There are four sections in the configuration file that are relevant to routing: the system.web.httpModules section, the system.web.httpHandlers section, the system.webserver.modules section, and the system.webserver.handlers section. Be careful not to delete these sections because without these sections routing will no longer work.

Second, and more importantly, a route table is created in the application's Global.asax file. The Global.asax file is a special file that contains event handlers for ASP.NET application lifecycle events. The route table is created during the Application Start event.

The file in Listing 1 contains the default Global.asax file for an ASP.NET MVC application.

Listing 1 - Global.asax.cs

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using System.Web.Mvc;
using System.Web.Routing;

namespace MvcApplication1
{
    // Note: For instructions on enabling IIS6 or IIS7 classic mode,
    // visit https://go.microsoft.com/?LinkId=9394801

    public class MvcApplication : System.Web.HttpApplication
    {
        public static void RegisterRoutes(RouteCollection routes)
        {
            routes.IgnoreRoute("{resource}.axd/{*pathInfo}");

            routes.MapRoute(
                "Default",                                          // Route name
                "{controller}/{action}/{id}",                       // URL with parameters
                new { controller = "Home", action = "Index", id = "" }  // Parameter defaults
            );
        }

        protected void Application_Start()
        {
            RegisterRoutes(RouteTable.Routes);
        }
    }
}
```

When an MVC application first starts, the Application_Start() method is called. This method, in turn, calls the RegisterRoutes() method. The RegisterRoutes() method creates the route table.

The default route table contains a single route (named Default). The Default route maps the first segment of a URL to a controller name, the second segment of a URL to a controller action, and the third segment to a parameter named **id**.

Imagine that you enter the following URL into your web browser's address bar:

/Home/Index/3

The Default route maps this URL to the following parameters:

- controller = Home
- action = Index
- id = 3

When you request the URL /Home/Index/3, the following code is executed:

HomeController.Index(3)

The Default route includes defaults for all three parameters. If you don't supply a controller, then the controller parameter defaults to the value **Home**. If you don't supply an action, the action parameter defaults to the value **Index**. Finally, if you don't supply an id, the id parameter defaults to an empty string.

Let's look at a few examples of how the Default route maps URLs to controller actions. Imagine that you enter the following URL into your browser address bar:

/Home

Because of the Default route parameter defaults, entering this URL will cause the Index() method of the HomeController class in Listing 2 to be called.

Listing 2 - HomeController.cs

```
using System.Web.Mvc;

namespace MvcApplication1.Controllers
{
    [HandleError]
    public class HomeController : Controller
    {
        public ActionResult Index(string id)
        {
            return View();
        }
    }
}
```

In Listing 2, the HomeController class includes a method named Index() that accepts a single parameter named Id. The URL /Home causes the Index() method to be called with an empty string as the value of the Id parameter.

Because of the way that the MVC framework invokes controller actions, the URL /Home also matches the Index() method of the HomeController class in Listing 3.

Listing 3 - HomeController.cs (Index action with no parameter)

```
using System.Web.Mvc;

namespace MvcApplication1.Controllers
{
    [HandleError]
    public class HomeController : Controller
    {
        public ActionResult Index()
        {
            return View();
        }
    }
}
```

The Index() method in Listing 3 does not accept any parameters. The URL /Home will cause this Index() method to be called. The URL /Home/Index/3 also invokes this method (the Id is ignored).

The URL /Home also matches the Index() method of the HomeController class in Listing 4.

Listing 4 - HomeController.cs (Index action with nullable parameter)

```
using System.Web.Mvc;

namespace MvcApplication1.Controllers
{
    [HandleError]
    public class HomeController : Controller
    {
        public ActionResult Index(int? id)
        {
            return View();
        }
    }
}
```

In Listing 4, the Index() method has one Integer parameter. Because the parameter is a nullable parameter (can have the value Null), the Index() can be called without raising an error.

Finally, invoking the Index() method in Listing 5 with the URL /Home causes an exception since the Id parameter *is not* a nullable parameter. If you attempt to invoke the Index() method then you get the error displayed in Figure 1.

Listing 5 - HomeController.cs (Index action with Id parameter)

```
using System.Web.Mvc;

namespace MvcApplication1.Controllers
{
    [HandleError]
    public class HomeController : Controller
    {
        public ActionResult Index(int id)
        {
            return View();
        }
    }
}
```

Figure 01: Invoking a controller action that expects a parameter value (Click to view full-size image)

The URL /Home/Index/3, on the other hand, works just fine with the Index controller action in Listing 5. The request /Home/Index/3 causes the Index() method to be called with an Id parameter that has the value 3.

Summary

The goal of this tutorial was to provide you with a brief introduction to ASP.NET Routing. We examined the default route table that you get with a new ASP.NET MVC application. You learned how the default route maps URLs to controller actions.

Understanding Action Filters (C#)

4/10/2020 • 6 minutes to read • Edit Online

by Microsoft

Download PDF

> The goal of this tutorial is to explain action filters. An action filter is an attribute that you can apply to a controller action -- or an entire controller -- that modifies the way in which the action is executed.

Understanding Action Filters

The goal of this tutorial is to explain action filters. An action filter is an attribute that you can apply to a controller action -- or an entire controller -- that modifies the way in which the action is executed. The ASP.NET MVC framework includes several action filters:

- OutputCache – This action filter caches the output of a controller action for a specified amount of time.
- HandleError – This action filter handles errors raised when a controller action executes.
- Authorize – This action filter enables you to restrict access to a particular user or role.

You also can create your own custom action filters. For example, you might want to create a custom action filter in order to implement a custom authentication system. Or, you might want to create an action filter that modifies the view data returned by a controller action.

In this tutorial, you learn how to build an action filter from the ground up. We create a Log action filter that logs different stages of the processing of an action to the Visual Studio Output window.

Using an Action Filter

An action filter is an attribute. You can apply most action filters to either an individual controller action or an entire controller.

For example, the Data controller in Listing 1 exposes an action named `Index()` that returns the current time. This action is decorated with the `OutputCache` action filter. This filter causes the value returned by the action to be cached for 10 seconds.

Listing 1 – `Controllers\DataController.cs`

```
using System;
using System.Web.Mvc;

namespace MvcApplication1.Controllers
{
     public class DataController : Controller
     {
          [OutputCache(Duration=10)]
          public string Index()
          {
               return DateTime.Now.ToString("T");
          }
     }
}
```

If you repeatedly invoke the `Index()` action by entering the URL /Data/Index into the address bar of your browser and hitting the Refresh button multiple times, then you will see the same time for 10 seconds. The output of the

`Index()` action is cached for 10 seconds (see Figure 1).

Figure 01: Cached time (Click to view full-size image)

In Listing 1, a single action filter – the `OutputCache` action filter – is applied to the `Index()` method. If you need, you can apply multiple action filters to the same action. For example, you might want to apply both the `OutputCache` and `HandleError` action filters to the same action.

In Listing 1, the `OutputCache` action filter is applied to the `Index()` action. You also could apply this attribute to the `DataController` class itself. In that case, the result returned by any action exposed by the controller would be cached for 10 seconds.

The Different Types of Filters

The ASP.NET MVC framework supports four different types of filters:

1. Authorization filters – Implements the `IAuthorizationFilter` attribute.
2. Action filters – Implements the `IActionFilter` attribute.
3. Result filters – Implements the `IResultFilter` attribute.
4. Exception filters – Implements the `IExceptionFilter` attribute.

Filters are executed in the order listed above. For example, authorization filters are always executed before action filters and exception filters are always executed after every other type of filter.

Authorization filters are used to implement authentication and authorization for controller actions. For example, the Authorize filter is an example of an Authorization filter.

Action filters contain logic that is executed before and after a controller action executes. You can use an action filter, for instance, to modify the view data that a controller action returns.

Result filters contain logic that is executed before and after a view result is executed. For example, you might want to modify a view result right before the view is rendered to the browser.

Exception filters are the last type of filter to run. You can use an exception filter to handle errors raised by either your controller actions or controller action results. You also can use exception filters to log errors.

Each different type of filter is executed in a particular order. If you want to control the order in which filters of the same type are executed then you can set a filter's Order property.

The base class for all action filters is the `System.Web.Mvc.FilterAttribute` class. If you want to implement a particular type of filter, then you need to create a class that inherits from the base Filter class and implements one or more of the `IAuthorizationFilter`, `IActionFilter`, `IResultFilter`, or `IExceptionFilter` interfaces.

The Base ActionFilterAttribute Class

In order to make it easier for you to implement a custom action filter, the ASP.NET MVC framework includes a base `ActionFilterAttribute` class. This class implements both the `IActionFilter` and `IResultFilter` interfaces and inherits from the `Filter` class.

The terminology here is not entirely consistent. Technically, a class that inherits from the ActionFilterAttribute class is both an action filter and a result filter. However, in the loose sense, the word action filter is used to refer to any type of filter in the ASP.NET MVC framework.

The base `ActionFilterAttribute` class has the following methods that you can override:

- OnActionExecuting – This method is called before a controller action is executed.
- OnActionExecuted – This method is called after a controller action is executed.
- OnResultExecuting – This method is called before a controller action result is executed.
- OnResultExecuted – This method is called after a controller action result is executed.

In the next section, we'll see how you can implement each of these different methods.

Creating a Log Action Filter

In order to illustrate how you can build a custom action filter, we'll create a custom action filter that logs the stages of processing a controller action to the Visual Studio Output window. Our `LogActionFilter` is contained in Listing 2.

Listing 2 – `ActionFilters\LogActionFilter.cs`

```
using System;
using System.Diagnostics;
using System.Web.Mvc;
using System.Web.Routing;

namespace MvcApplication1.ActionFilters
{
     public class LogActionFilter : ActionFilterAttribute

     {
          public override void OnActionExecuting(ActionExecutingContext filterContext)
          {
               Log("OnActionExecuting", filterContext.RouteData);
          }

          public override void OnActionExecuted(ActionExecutedContext filterContext)
          {
               Log("OnActionExecuted", filterContext.RouteData);
          }

          public override void OnResultExecuting(ResultExecutingContext filterContext)
          {
               Log("OnResultExecuting", filterContext.RouteData);
          }

          public override void OnResultExecuted(ResultExecutedContext filterContext)
          {
               Log("OnResultExecuted", filterContext.RouteData);
          }

          private void Log(string methodName, RouteData routeData)
          {
               var controllerName = routeData.Values["controller"];
               var actionName = routeData.Values["action"];
               var message = String.Format("{0} controller:{1} action:{2}", methodName, controllerName,
actionName);
               Debug.WriteLine(message, "Action Filter Log");
          }

     }
}
```

In Listing 2, the `OnActionExecuting()`, `OnActionExecuted()`, `OnResultExecuting()`, and `OnResultExecuted()` methods all call the `Log()` method. The name of the method and the current route data is passed to the `Log()` method. The `Log()` method writes a message to the Visual Studio Output window (see Figure 2).

Figure 02: Writing to the Visual Studio Output window (Click to view full-size image)

The Home controller in Listing 3 illustrates how you can apply the Log action filter to an entire controller class. Whenever any of the actions exposed by the Home controller are invoked – either the `Index()` method or the `About()` method – the stages of processing the action are logged to the Visual Studio Output window.

Listing 3 – `Controllers\HomeController.cs`

```
using System.Web.Mvc;
using MvcApplication1.ActionFilters;

namespace MvcApplication1.Controllers
{
    [LogActionFilter]
    public class HomeController : Controller
    {
        public ActionResult Index()
        {
            return View();
        }

        public ActionResult About()
        {
            return View();
        }
    }
}
```

Summary

In this tutorial, you were introduced to ASP.NET MVC action filters. You learned about the four different types of filters: authorization filters, action filters, result filters, and exception filters. You also learned about the base `ActionFilterAttribute` class.

Finally, you learned how to implement a simple action filter. We created a Log action filter that logs the stages of processing a controller action to the Visual Studio Output window.

Improving Performance with Output Caching (C#)

4/10/2020 • 9 minutes to read • Edit Online

by Microsoft

> In this tutorial, you learn how you can dramatically improve the performance of your ASP.NET MVC web applications by taking advantage of output caching. You learn how to cache the result returned from a controller action so that the same content does not need to be created each and every time a new user invokes the action.

The goal of this tutorial is to explain how you can dramatically improve the performance of an ASP.NET MVC application by taking advantage of the output cache. The output cache enables you to cache the content returned by a controller action. That way, the same content does not need to be generated each and every time the same controller action is invoked.

Imagine, for example, that your ASP.NET MVC application displays a list of database records in a view named Index. Normally, each and every time that a user invokes the controller action that returns the Index view, the set of database records must be retrieved from the database by executing a database query.

If, on the other hand, you take advantage of the output cache then you can avoid executing a database query every time any user invokes the same controller action. The view can be retrieved from the cache instead of being regenerated from the controller action. Caching enables you to avoid performing redundant work on the server.

Enabling Output Caching

You enable output caching by adding an [OutputCache] attribute to either an individual controller action or an entire controller class. For example, the controller in Listing 1 exposes an action named Index(). The output of the Index() action is cached for 10 seconds.

Listing 1 – Controllers\HomeController.cs

```
using System.Web.Mvc;

namespace MvcApplication1.Controllers
{
    [HandleError]
    public class HomeController : Controller
    {
        [OutputCache(Duration=10, VaryByParam="none")]
        public ActionResult Index()
        {
            return View();
        }
    }
}
```

In the Beta versions of ASP.NET MVC, output caching does not work for a URL like http://www.MySite.com/. Instead, you must enter a URL like http://www.MySite.com/Home/Index.

In Listing 1, the output of the Index() action is cached for 10 seconds. If you prefer, you can specify a much longer cache duration. For example, if you want to cache the output of a controller action for one day then you can specify a cache duration of 86400 seconds (60 seconds * 60 minutes * 24 hours).

There is no guarantee that content will be cached for the amount of time that you specify. When memory resources become low, the cache starts evicting content automatically.

The Home controller in Listing 1 returns the Index view in Listing 2. There is nothing special about this view. The Index view simply displays the current time (see Figure 1).

Listing 2 – Views\Home\Index.aspx

```
<%@ Page Language="C#" AutoEventWireup="true" CodeBehind="Index.aspx.cs"
Inherits="MvcApplication1.Views.Home.Index" %>
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-
transitional.dtd">
<html xmlns="http://www.w3.org/1999/xhtml" >
<head runat="server">
    <title>Index</title>
</head>
<body>
    <div>

    The current time is: <%= DateTime.Now.ToString("T") %>

    </div>
</body>
</html>
```

Figure 1 – Cached Index view

If you invoke the Index() action multiple times by entering the URL /Home/Index in the address bar of your browser and hitting the Refresh/Reload button in your browser repeatedly, then the time displayed by the Index view won't change for 10 seconds. The same time is displayed because the view is cached.

It is important to understand that the same view is cached for everyone who visits your application. Anyone who invokes the Index() action will get the same cached version of the Index view. This means that the amount of work that the web server must perform to serve the Index view is dramatically reduced.

The view in Listing 2 happens to be doing something really simple. The view just displays the current time. However, you could just as easily cache a view that displays a set of database records. In that case, the set of database records would not need to be retrieved from the database each and every time the controller action that returns the view is invoked. Caching can reduce the amount of work that both your web server and database server must perform.

Don't use the page <%@ OutputCache %> directive in an MVC view. This directive is bleeding over from the Web Forms world and should not be used in an ASP.NET MVC application.

Where Content is Cached

By default, when you use the [OutputCache] attribute, content is cached in three locations: the web server, any

proxy servers, and the web browser. You can control exactly where content is cached by modifying the Location property of the [OutputCache] attribute.

You can set the Location property to any one of the following values:

- Any
- Client
- Downstream
- Server
- None
- ServerAndClient

By default, the Location property has the value Any. However, there are situations in which you might want to cache only on the browser or only on the server. For example, if you are caching information that is personalized for each user then you should not cache the information on the server. If you are displaying different information to different users then you should cache the information only on the client.

For example, the controller in Listing 3 exposes an action named GetName() that returns the current user name. If Jack logs into the website and invokes the GetName() action then the action returns the string "Hi Jack". If, subsequently, Jill logs into the website and invokes the GetName() action then she also will get the string "Hi Jack". The string is cached on the web server for all users after Jack initially invokes the controller action.

Listing 3 – Controllers\BadUserController.cs

```
using System.Web.Mvc;
using System.Web.UI;

namespace MvcApplication1.Controllers
{
    public class BadUserController : Controller
    {
        [OutputCache(Duration = 3600, VaryByParam = "none")]
        public string GetName()
        {
            return "Hi " + User.Identity.Name;
        }
    }
}
```

Most likely, the controller in Listing 3 does not work the way that you want. You don't want to display the message "Hi Jack" to Jill.

You should never cache personalized content in the server cache. However, you might want to cache the personalized content in the browser cache to improve performance. If you cache content in the browser, and a user invokes the same controller action multiple times, then the content can be retrieved from the browser cache instead of the server.

The modified controller in Listing 4 caches the output of the GetName() action. However, the content is cached only on the browser and not on the server. That way, when multiple users invoke the GetName() method, each person gets their own user name and not another person's user name.

Listing 4 – Controllers\UserController.cs

```
using System.Web.Mvc;
using System.Web.UI;

namespace MvcApplication1.Controllers
{
    public class UserController : Controller
    {
        [OutputCache(Duration=3600, VaryByParam="none", Location=OutputCacheLocation.Client, NoStore=true)]
        public string GetName()
        {
            return "Hi " + User.Identity.Name;
        }
    }
}
```

Notice that the [OutputCache] attribute in Listing 4 includes a Location property set to the value OutputCacheLocation.Client. The [OutputCache] attribute also includes a NoStore property. The NoStore property is used to inform proxy servers and browser that they should not store a permanent copy of the cached content.

Varying the Output Cache

In some situations, you might want different cached versions of the very same content. Imagine, for example, that you are creating a master/detail page. The master page displays a list of movie titles. When you click a title, you get details for the selected movie.

If you cache the details page, then the details for the same movie will be displayed no matter which movie you click. The first movie selected by the first user will be displayed to all future users.

You can fix this problem by taking advantage of the VaryByParam property of the [OutputCache] attribute. This property enables you to create different cached versions of the very same content when a form parameter or query string parameter varies.

For example, the controller in Listing 5 exposes two actions named Master() and Details(). The Master() action returns a list of movie titles and the Details() action returns the details for the selected movie.

Listing 5 – Controllers\MoviesController.cs

```
using System.Linq;
using System.Web.Mvc;
using MvcApplication1.Models;

namespace MvcApplication1.Controllers
{
    public class MoviesController : Controller
    {
        private MovieDataContext _dataContext;

        public MoviesController()
        {
            _dataContext = new MovieDataContext();
        }

        [OutputCache(Duration=int.MaxValue, VaryByParam="none")]
        public ActionResult Master()
        {
            ViewData.Model = (from m in _dataContext.Movies
                              select m).ToList();
            return View();
        }

        [OutputCache(Duration = int.MaxValue, VaryByParam = "id")]
        public ActionResult Details(int id)
        {
            ViewData.Model = _dataContext.Movies.SingleOrDefault(m => m.Id == id);
            return View();
        }

    }
}
```

The Master() action includes a VaryByParam property with the value "none". When the Master() action is invoked, the same cached version of the Master view is returned. Any form parameters or query string parameters are ignored (see Figure 2).

Figure 2 – The /Movies/Master view

Figure 3 – The /Movies/Details view

The Details() action includes a VaryByParam property with the value "Id". When different values of the Id parameter are passed to the controller action, different cached versions of the Details view are generated.

It is important to understand that using the VaryByParam property results in more caching and not less. A different cached version of the Details view is created for each different version of the Id parameter.

You can set the VaryByParam property to the following values:

> * = Create a different cached version whenever a form or query string parameter varies.
>
> none = Never create different cached versions
>
> Semicolon list of parameters = Create different cached versions whenever any of the form or query string parameters in the list varies

Creating a Cache Profile

As an alternative to configuring output cache properties by modifying properties of the [OutputCache] attribute, you can create a cache profile in the web configuration (web.config) file. Creating a cache profile in the web configuration file offers a couple of important advantages.

First, by configuring output caching in the web configuration file, you can control how controller actions cache content in one central location. You can create one cache profile and apply the profile to several controllers or controller actions.

Second, you can modify the web configuration file without recompiling your application. If you need to disable caching for an application that has already been deployed to production, then you can simply modify the cache profiles defined in the web configuration file. Any changes to the web configuration file will be detected automatically and applied.

For example, the <caching> web configuration section in Listing 6 defines a cache profile named Cache1Hour. The <caching> section must appear within the <system.web> section of a web configuration file.

Listing 6 – Caching section for web.config

```
<caching>
<outputCacheSettings>
    <outputCacheProfiles>
        <add name="Cache1Hour" duration="3600" varyByParam="none"/>
    </outputCacheProfiles>
</outputCacheSettings>
</caching>
```

The controller in Listing 7 illustrates how you can apply the Cache1Hour profile to a controller action with the [OutputCache] attribute.

Listing 7 – Controllers\ProfileController.cs

```
using System;
using System.Web.Mvc;

namespace MvcApplication1.Controllers
{
    public class ProfileController : Controller
    {
        [OutputCache(CacheProfile="Cache1Hour")]
        public string Index()
        {
            return DateTime.Now.ToString("T");
        }
    }
}
```

If you invoke the Index() action exposed by the controller in Listing 7 then the same time will be returned for 1 hour.

Summary

Output caching provides you with a very easy method of dramatically improving the performance of your ASP.NET MVC applications. In this tutorial, you learned how to use the [OutputCache] attribute to cache the output of controller actions. You also learned how to modify properties of the [OutputCache] attribute such as the Duration and VaryByParam properties to modify how content gets cached. Finally, you learned how to define cache profiles in the web configuration file.

Adding Dynamic Content to a Cached Page (C#)

4/10/2020 • 5 minutes to read • Edit Online

by Microsoft

Learn how to mix dynamic and cached content in the same page. Post-cache substitution enables you to display dynamic content, such as banner advertisements or news items, within a page that has been output cached.

By taking advantage of output caching, you can dramatically improve the performance of an ASP.NET MVC application. Instead of regenerating a page each and every time the page is requested, the page can be generated once and cached in memory for multiple users.

But there is a problem. What if you need to display dynamic content in the page? For example, imagine that you want to display a banner advertisement in the page. You don't want the banner advertisement to be cached so that every user sees the very same advertisement. You wouldn't make any money that way!

Fortunately, there is an easy solution. You can take advantage of a feature of the ASP.NET framework called *post-cache substitution*. Post-cache substitution enables you to substitute dynamic content in a page that has been cached in memory.

Normally, when you output cache a page by using the [OutputCache] attribute, the page is cached on both the server and the client (the web browser). When you use post-cache substitution, a page is cached only on the server.

Using Post-Cache Substitution

Using post-cache substitution requires two steps. First, you need to define a method that returns a string that represents the dynamic content that you want to display in the cached page. Next, you call the HttpResponse.WriteSubstitution() method to inject the dynamic content into the page.

Imagine, for example, that you want to randomly display different news items in a cached page. The class in Listing 1 exposes a single method, named RenderNews(), that randomly returns one news item from a list of three news items.

Listing 1 – Models\News.cs

```
using System;
using System.Collections.Generic;
using System.Web;

namespace MvcApplication1.Models
{
    public class News
    {
        public static string RenderNews(HttpContext context)
        {
            var news = new List<string>
                {
                    "Gas prices go up!",
                    "Life discovered on Mars!",
                    "Moon disappears!"
                };

            var rnd = new Random();
            return news[rnd.Next(news.Count)];
        }
    }
}
```

To take advantage of post-cache substitution, you call the HttpResponse.WriteSubstitution() method. The WriteSubstitution() method sets up the code to replace a region of the cached page with dynamic content. The WriteSubstitution() method is used to display the random news item in the view in Listing 2.

Listing 2 – Views\Home\Index.aspx

```
<%@ Page Language="C#" AutoEventWireup="true" CodeBehind="Index.aspx.cs"
Inherits="MvcApplication1.Views.Home.Index" %>
<%@ Import Namespace="MvcApplication1.Models" %>
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-
transitional.dtd">
<html xmlns="http://www.w3.org/1999/xhtml" >
<head runat="server">
    <title>Index</title>
</head>
<body>
    <div>

    <% Response.WriteSubstitution(News.RenderNews); %>

    <hr />

    The content of this page is output cached.
    <%= DateTime.Now %>

    </div>
</body>
</html>
```

The RenderNews method is passed to the WriteSubstitution() method. Notice that the RenderNews method is not called (there are no parentheses). Instead a reference to the method is passed to WriteSubstitution().

The Index view is cached. The view is returned by the controller in Listing 3. Notice that the Index() action is decorated with an [OutputCache] attribute that causes the Index view to be cached for 60 seconds.

Listing 3 – Controllers\HomeController.cs

```
using System.Web.Mvc;

namespace MvcApplication1.Controllers
{
    [HandleError]
    public class HomeController : Controller
    {
        [OutputCache(Duration=60, VaryByParam="none")]
        public ActionResult Index()
        {
            return View();
        }
    }
}
```

Even though the Index view is cached, different random news items are displayed when you request the Index page. When you request the Index page, the time displayed by the page does not change for 60 seconds (see Figure 1). The fact that the time does not change proves that the page is cached. However, the content injected by the WriteSubstitution() method – the random news item – changes with each request .

Figure 1 – Injecting dynamic news items in a cached page

Using Post-Cache Substitution in Helper Methods

An easier way to take advantage of post-cache substitution is to encapsulate the call to the WriteSubstitution() method within a custom helper method. This approach is illustrated by the helper method in Listing 4.

Listing 4 – AdHelper.cs

```
using System;
using System.Collections.Generic;
using System.Web;
using System.Web.Mvc;

namespace MvcApplication1.Helpers
{
    public static class AdHelper
    {
        public static void RenderBanner(this HtmlHelper helper)
        {
            var context = helper.ViewContext.HttpContext;
            context.Response.WriteSubstitution(RenderBannerInternal);
        }

        private static string RenderBannerInternal(HttpContext context)
        {
            var ads = new List<string>
                {
                    "/ads/banner1.gif",
                    "/ads/banner2.gif",
                    "/ads/banner3.gif"
                };

            var rnd = new Random();
            var ad = ads[rnd.Next(ads.Count)];
            return String.Format("<img src='{0}' />", ad);
        }
    }
}
```

Listing 4 contains a static class that exposes two methods: RenderBanner() and RenderBannerInternal(). The RenderBanner() method represents the actual helper method. This method extends the standard ASP.NET MVC HtmlHelper class so that you can call Html.RenderBanner() in a view just like any other helper method.

The RenderBanner() method calls the HttpResponse.WriteSubstitution() method passing the RenderBannerInternal() method to the WriteSubstitution() method.

The RenderBannerInternal() method is a private method. This method won't be exposed as a helper method. The RenderBannerInternal() method randomly returns one banner advertisement image from a list of three banner advertisement images.

The modified Index view in Listing 5 illustrates how you can use the RenderBanner() helper method. Notice that an additional <%@ Import %> directive is included at the top of the view to import the MvcApplication1.Helpers namespace. If you neglect to import this namespace, then the RenderBanner() method won't appear as a method on the Html property.

Listing 5 – Views\Home\Index.aspx (with RenderBanner() method)

```
<%@ Page Language="C#" AutoEventWireup="true" CodeBehind="Index.aspx.cs"
Inherits="MvcApplication1.Views.Home.Index" %>
<%@ Import Namespace="MvcApplication1.Models" %>
<%@ Import Namespace="MvcApplication1.Helpers" %>
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-
transitional.dtd">
<html xmlns="http://www.w3.org/1999/xhtml" >
<head runat="server">
    <title>Index</title>
</head>
<body>
    <div>

    <% Response.WriteSubstitution(News.RenderNews); %>

    <hr />

    <% Html.RenderBanner(); %>

    <hr />

    The content of this page is output cached.
    <%= DateTime.Now %>

    </div>
</body>
</html>
```

When you request the page rendered by the view in Listing 5, a different banner advertisement is displayed with each request (see Figure 2). The page is cached, but the banner advertisement is injected dynamically by the RenderBanner() helper method.

Figure 2 – The Index view displaying a random banner advertisement

Summary

This tutorial explained how you can dynamically update content in a cached page. You learned how to use the HttpResponse.WriteSubstitution() method to enable dynamic content to be injected in a cached page. You also learned how to encapsulate the call to the WriteSubstitution() method within an HTML helper method.

Take advantage of caching whenever possible – it can have a dramatic impact on the performance of your web applications. As explained in this tutorial, you can take advantage of caching even when you need to display

dynamic content in your pages.

Creating a Controller (C#)

2/20/2020 • 3 minutes to read • Edit Online

by Stephen Walther

In this tutorial, Stephen Walther demonstrates how you can add a controller to an ASP.NET MVC application.

The goal of this tutorial is to explain how you can create new ASP.NET MVC controllers. You learn how to create controllers both by using the Visual Studio Add Controller menu option and by creating a class file by hand.

Using the Add Controller Menu Option

The easiest way to create a new controller is to right-click the Controllers folder in the Visual Studio Solution Explorer window and select the **Add, Controller** menu option (see Figure 1). Selecting this menu option opens the **Add Controller** dialog (see Figure 2).

Figure 01: Adding a new controller(Click to view full-size image)

Figure 02: The Add Controller dialog (Click to view full-size image)

Notice that the first part of the controller name is highlighted in the **Add Controller** dialog. Every controller name must end with the suffix *Controller*. For example, you can create a controller named *ProductController* but not a controller named *Product*.

If you create a controller that is missing the *Controller* suffix then you won't be able to invoke the controller. Don't do this -- I've wasted countless hours of my life after making this mistake.

Listing 1 - Controllers\ProductController.cs

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using System.Web.Mvc;
using System.Web.Mvc.Ajax;

namespace MvcApplication1.Controllers
{
    public class ProductController : Controller
    {
        //
        // GET: /Product/

        public ActionResult Index()
        {
            return View();
        }
    }
}
```

You should always create controllers in the Controllers folder. Otherwise, you'll be violating the conventions of ASP.NET MVC and other developers will have a more difficult time understanding your application.

Scaffolding Action Methods

When you create a controller, you have the option to generate Create, Update, and Details action methods automatically (see Figure 3). If you select this option then the controller class in Listing 2 is generated.

Figure 03: Creating action methods automatically (Click to view full-size image)

Listing 2 - Controllers\CustomerController.cs

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using System.Web.Mvc;
using System.Web.Mvc.Ajax;

namespace MvcApplication1.Controllers
{
    public class CustomerController : Controller
    {
        //
        // GET: /Customer/

        public ActionResult Index()
        {
            return View();
        }

        //
        // GET: /Customer/Details/5

        public ActionResult Details(int id)
```

```
        {
            return View();
        }

        //
        // GET: /Customer/Create

        public ActionResult Create()
        {
            return View();
        }

        //
        // POST: /Customer/Create

        [AcceptVerbs(HttpVerbs.Post)]
        public ActionResult Create(FormCollection collection)
        {
            try
            {
                // TODO: Add insert logic here

                return RedirectToAction("Index");
            }
            catch
            {
                return View();
            }
        }

        //
        // GET: /Customer/Edit/5

        public ActionResult Edit(int id)
        {
            return View();
        }

        //
        // POST: /Customer/Edit/5

        [AcceptVerbs(HttpVerbs.Post)]
        public ActionResult Edit(int id, FormCollection collection)
        {
            try
            {
                // TODO: Add update logic here

                return RedirectToAction("Index");
            }
            catch
            {
                return View();
            }
        }
    }
}
```

These generated methods are stub methods. You must add the actual logic for creating, updating, and showing details for a customer yourself. But, the stub methods provide you with a nice starting point.

Creating a Controller Class

The ASP.NET MVC controller is just a class. If you prefer, you can ignore the convenient Visual Studio controller scaffolding and create a controller class by hand. Follow these steps:

1. Right-click the Controllers folder and select the menu option **Add, New Item** and select the **Class** template

(see Figure 4).

2. Name the new class PersonController.cs and click the **Add** button.
3. Modify the resulting class file so that the class inherits from the base System.Web.Mvc.Controller class (see Listing 3).

Figure 04: Creating a new class(Click to view full-size image)

Listing 3 - Controllers\PersonController.cs

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;

namespace MvcApplication1.Controllers
{
    public class PersonController : System.Web.Mvc.Controller
    {
        public string Index()
        {
            return "Hello World!";
        }
    }
}
```

The controller in Listing 3 exposes one action named Index() that returns the string "Hello World!". You can invoke this controller action by running your application and requesting a URL like the following:

```
http://localhost:40071/Person
```

NOTE

The ASP.NET Development Server uses a random port number (for example, 40071). When entering a URL to invoke a controller, you'll need to supply the right port number. You can determine the port number by hovering your mouse over the icon for the ASP.NET Development Server in the Windows Notification Area (bottom-right of your screen).

Creating an Action (C#)

4/10/2020 • 2 minutes to read • Edit Online

by Microsoft

> Learn how to add a new action to an ASP.NET MVC controller. Learn about the requirements for a method to be an action.

The goal of this tutorial is to explain how you can create a new controller action. You learn about the requirements of an action method. You also learn how to prevent a method from being exposed as an action.

Adding an Action to a Controller

You add a new action to a controller by adding a new method to the controller. For example, the controller in Listing 1 contains an action named Index() and an action named SayHello(). Both methods are exposed as actions.

Listing 1 - Controllers\HomeController.cs

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using System.Web.Mvc;

namespace MvcApplication1.Controllers
{
    [HandleError]
    public class HomeController : Controller
    {
        public ActionResult Index()
        {
            return View();
        }

        public string SayHello()
        {
            return "Hello!";
        }
    }
}
```

In order to be exposed to the universe as an action, a method must meet certain requirements:

- The method must be public.
- The method cannot be a static method.
- The method cannot be an extension method.
- The method cannot be a constructor, getter, or setter.
- The method cannot have open generic types.
- The method is not a method of the controller base class.
- The method cannot contain **ref** or **out** parameters.

Notice that there are no restrictions on the return type of a controller action. A controller action can return a string, a DateTime, an instance of the Random class, or void. The ASP.NET MVC framework will convert any return type that is not an action result into a string and render the string to the browser.

When you add any method that does not violate these requirements to a controller, the method is exposed as a controller action. Be careful here. A controller action can be invoked by anyone connected to the Internet. Do not, for example, create a DeleteMyWebsite() controller action.

Preventing a Public Method from Being Invoked

If you need to create a public method in a controller class and you don't want to expose the method as a controller action then you can prevent the method from being invoked by using the [NonAction] attribute. For example, the controller in Listing 2 contains a public method named CompanySecrets() that is decorated with the [NonAction] attribute.

Listing 2 - Controllers\WorkController.cs

```
using System.Web.Mvc;

namespace MvcApplication1.Controllers
{
    public class WorkController : Controller
    {
        [NonAction]
        public string CompanySecrets()
        {
            return "This information is secret.";
        }
    }
}
```

If you attempt to invoke the CompanySecrets() controller action by typing /Work/CompanySecrets into the address bar of your browser then you'll get the error message in Figure 1.

Figure 01: Invoking a NonAction method(Click to view full-size image)

ASP.NET MVC Routing Overview (VB)

2/20/2020 • 4 minutes to read • Edit Online

by Stephen Walther

> In this tutorial, Stephen Walther shows how the ASP.NET MVC framework maps browser requests to controller actions.

In this tutorial, you are introduced to an important feature of every ASP.NET MVC application called *ASP.NET Routing*. The ASP.NET Routing module is responsible for mapping incoming browser requests to particular MVC controller actions. By the end of this tutorial, you will understand how the standard route table maps requests to controller actions.

Using the Default Route Table

When you create a new ASP.NET MVC application, the application is already configured to use ASP.NET Routing. ASP.NET Routing is setup in two places.

First, ASP.NET Routing is enabled in your application's Web configuration file (Web.config file). There are four sections in the configuration file that are relevant to routing: the system.web.httpModules section, the system.web.httpHandlers section, the system.webserver.modules section, and the system.webserver.handlers section. Be careful not to delete these sections because without these sections routing will no longer work.

Second, and more importantly, a route table is created in the application's Global.asax file. The Global.asax file is a special file that contains event handlers for ASP.NET application lifecycle events. The route table is created during the Application Start event.

The file in Listing 1 contains the default Global.asax file for an ASP.NET MVC application.

Listing 1 - Global.asax.vb

```
' Note: For instructions on enabling IIS6 or IIS7 classic mode,
' visit https://go.microsoft.com/?LinkId=9394802

Public Class MvcApplication
    Inherits System.Web.HttpApplication

    Shared Sub RegisterRoutes(ByVal routes As RouteCollection)
        routes.IgnoreRoute("{resource}.axd/{*pathInfo}")

        ' MapRoute takes the following parameters, in order:
        ' (1) Route name
        ' (2) URL with parameters
        ' (3) Parameter defaults
        routes.MapRoute( _
            "Default", _
            "{controller}/{action}/{id}", _
            New With {.controller = "Home", .action = "Index", .id = ""} _
        )

    End Sub

    Sub Application_Start()
        RegisterRoutes(RouteTable.Routes)
    End Sub
End Class
```

When an MVC application first starts, the Application_Start() method is called. This method, in turn, calls the RegisterRoutes() method. The RegisterRoutes() method creates the route table.

The default route table contains a single route (named Default). The Default route maps the first segment of a URL to a controller name, the second segment of a URL to a controller action, and the third segment to a parameter named **id**.

Imagine that you enter the following URL into your web browser's address bar:

/Home/Index/3

The Default route maps this URL to the following parameters:

- controller = Home
- action = Index
- id = 3

When you request the URL /Home/Index/3, the following code is executed:

HomeController.Index(3)

The Default route includes defaults for all three parameters. If you don't supply a controller, then the controller parameter defaults to the value **Home**. If you don't supply an action, the action parameter defaults to the value **Index**. Finally, if you don't supply an id, the id parameter defaults to an empty string.

Let's look at a few examples of how the Default route maps URLs to controller actions. Imagine that you enter the following URL into your browser address bar:

/Home

Because of the Default route parameter defaults, entering this URL will cause the Index() method of the HomeController class in Listing 2 to be called.

Listing 2 - HomeController.vb

```
<HandleError()> _
Public Class HomeController
    Inherits System.Web.Mvc.Controller

    Function Index(ByVal id As String)
        Return View()
    End Function

End Class
```

In Listing 2, the HomeController class includes a method named Index() that accepts a single parameter named Id. The URL /Home causes the Index() method to be called with the value Nothing as the value of the Id parameter.

Because of the way that the MVC framework invokes controller actions, the URL /Home also matches the Index() method of the HomeController class in Listing 3.

Listing 3 - HomeController.vb (Index action with no parameter)

```
<HandleError()> _
Public Class HomeController
    Inherits System.Web.Mvc.Controller

    Function Index()
        Return View()
    End Function

End Class
```

The Index() method in Listing 3 does not accept any parameters. The URL /Home will cause this Index() method to be called. The URL /Home/Index/3 also invokes this method (the Id is ignored).

The URL /Home also matches the Index() method of the HomeController class in Listing 4.

Listing 4 - HomeController.vb (Index action with nullable parameter)

```
<HandleError()> _
Public Class HomeController
    Inherits System.Web.Mvc.Controller

    Function Index(ByVal id? As Integer)
        Return View()
    End Function

End Class
```

In Listing 4, the Index() method has one Integer parameter. Because the parameter is a nullable parameter (can have the value Nothing), the Index() can be called without raising an error.

Finally, invoking the Index() method in Listing 5 with the URL /Home causes an exception since the Id parameter *is not* a nullable parameter. If you attempt to invoke the Index() method then you get the error displayed in Figure 1.

Listing 5 - HomeController.vb (Index action with Id parameter)

```
<HandleError()> _
Public Class HomeController
    Inherits System.Web.Mvc.Controller

    Function Index(ByVal id As Integer)
        Return View()
    End Function

End Class
```

Figure 01: Invoking a controller action that expects a parameter value (Click to view full-size image)

The URL /Home/Index/3, on the other hand, works just fine with the Index controller action in Listing 5. The request /Home/Index/3 causes the Index() method to be called with an Id parameter that has the value 3.

Summary

The goal of this tutorial was to provide you with a brief introduction to ASP.NET Routing. We examined the default route table that you get with a new ASP.NET MVC application. You learned how the default route maps URLs to controller actions.

Understanding Action Filters (VB)

4/10/2020 • 6 minutes to read • Edit Online

by Microsoft

Download PDF

> The goal of this tutorial is to explain action filters. An action filter is an attribute that you can apply to a controller action -- or an entire controller -- that modifies the way in which the action is executed.

Understanding Action Filters

The goal of this tutorial is to explain action filters. An action filter is an attribute that you can apply to a controller action -- or an entire controller -- that modifies the way in which the action is executed. The ASP.NET MVC framework includes several action filters:

- OutputCache – This action filter caches the output of a controller action for a specified amount of time.
- HandleError – This action filter handles errors raised when a controller action executes.
- Authorize – This action filter enables you to restrict access to a particular user or role.

You also can create your own custom action filters. For example, you might want to create a custom action filter in order to implement a custom authentication system. Or, you might want to create an action filter that modifies the view data returned by a controller action.

In this tutorial, you learn how to build an action filter from the ground up. We create a Log action filter that logs different stages of the processing of an action to the Visual Studio Output window.

Using an Action Filter

An action filter is an attribute. You can apply most action filters to either an individual controller action or an entire controller.

For example, the Data controller in Listing 1 exposes an action named `Index()` that returns the current time. This action is decorated with the `OutputCache` action filter. This filter causes the value returned by the action to be cached for 10 seconds.

Listing 1 – `Controllers\DataController.vb`

```
Public Class DataController
     Inherits System.Web.Mvc.Controller

     <OutputCache(Duration:=10)> _
     Function Index()
          Return DateTime.Now.ToString("T")

     End Function

End Class
```

If you repeatedly invoke the `Index()` action by entering the URL /Data/Index into the address bar of your browser and hitting the Refresh button multiple times, then you will see the same time for 10 seconds. The output of the `Index()` action is cached for 10 seconds (see Figure 1).

Figure 01: Cached time (Click to view full-size image)

In Listing 1, a single action filter – the `OutputCache` action filter – is applied to the `Index()` method. If you need, you can apply multiple action filters to the same action. For example, you might want to apply both the `OutputCache` and `HandleError` action filters to the same action.

In Listing 1, the `OutputCache` action filter is applied to the `Index()` action. You also could apply this attribute to the `DataController` class itself. In that case, the result returned by any action exposed by the controller would be cached for 10 seconds.

The Different Types of Filters

The ASP.NET MVC framework supports four different types of filters:

1. Authorization filters – Implements the `IAuthorizationFilter` attribute.
2. Action filters – Implements the `IActionFilter` attribute.
3. Result filters – Implements the `IResultFilter` attribute.
4. Exception filters – Implements the `IExceptionFilter` attribute.

Filters are executed in the order listed above. For example, authorization filters are always executed before action filters and exception filters are always executed after every other type of filter.

Authorization filters are used to implement authentication and authorization for controller actions. For example, the Authorize filter is an example of an Authorization filter.

Action filters contain logic that is executed before and after a controller action executes. You can use an action filter, for instance, to modify the view data that a controller action returns.

Result filters contain logic that is executed before and after a view result is executed. For example, you might want to modify a view result right before the view is rendered to the browser.

Exception filters are the last type of filter to run. You can use an exception filter to handle errors raised by either your controller actions or controller action results. You also can use exception filters to log errors.

Each different type of filter is executed in a particular order. If you want to control the order in which filters of the same type are executed then you can set a filter's Order property.

The base class for all action filters is the `System.Web.Mvc.FilterAttribute` class. If you want to implement a particular type of filter, then you need to create a class that inherits from the base Filter class and implements one or more of the IAuthorizationFilter, IActionFilter, IResultFilter, or ExceptionFilter interfaces.

The Base ActionFilterAttribute Class

In order to make it easier for you to implement a custom action filter, the ASP.NET MVC framework includes a base `ActionFilterAttribute` class. This class implements both the `IActionFilter` and `IResultFilter` interfaces and inherits from the `Filter` class.

The terminology here is not entirely consistent. Technically, a class that inherits from the ActionFilterAttribute class is both an action filter and a result filter. However, in the loose sense, the word action filter is used to refer to any

type of filter in the ASP.NET MVC framework.

The base ActionFilterAttribute class has the following methods that you can override:

- OnActionExecuting – This method is called before a controller action is executed.
- OnActionExecuted – This method is called after a controller action is executed.
- OnResultExecuting – This method is called before a controller action result is executed.
- OnResultExecuted – This method is called after a controller action result is executed.

In the next section, we'll see how you can implement each of these different methods.

Creating a Log Action Filter

In order to illustrate how you can build a custom action filter, we'll create a custom action filter that logs the stages of processing a controller action to the Visual Studio Output window. Our `LogActionFilter` is contained in Listing 2.

Listing 2 – `ActionFilters\LogActionFilter.vb`

```
Public Class LogActionFilter
     Inherits ActionFilterAttribute

     Public Overrides Sub OnActionExecuting(ByVal filterContext As ActionExecutingContext)
          Log("OnActionExecuting", filterContext.RouteData)

     End Sub

     Public Overrides Sub OnActionExecuted(ByVal filterContext As ActionExecutedContext)
          Log("OnActionExecuted", filterContext.RouteData)
     End Sub

     Public Overrides Sub OnResultExecuting(ByVal filterContext As ResultExecutingContext)
          Log("OnResultExecuting", filterContext.RouteData)
     End Sub

     Public Overrides Sub OnResultExecuted(ByVal filterContext As ResultExecutedContext)
          Log("OnResultExecuted", filterContext.RouteData)
     End Sub

     Private Sub Log(ByVal methodName As String, ByVal routeData As RouteData)
          Dim controllerName = routeData.Values("controller")
          Dim actionName = routeData.Values("action")
          Dim message = String.Format("{0} controller:{1} action:{2}", methodName, controllerName, actionName)
          Debug.WriteLine(message, "Action Filter Log")
     End Sub

End Class
```

In Listing 2, the `OnActionExecuting()`, `OnActionExecuted()`, `OnResultExecuting()`, and `OnResultExecuted()` methods all call the `Log()` method. The name of the method and the current route data is passed to the `Log()` method. The `Log()` method writes a message to the Visual Studio Output window (see Figure 2).

Figure 02: Writing to the Visual Studio Output window (Click to view full-size image)

The Home controller in Listing 3 illustrates how you can apply the Log action filter to an entire controller class. Whenever any of the actions exposed by the Home controller are invoked – either the `Index()` method or the `About()` method – the stages of processing the action are logged to the Visual Studio Output window.

Listing 3 – `Controllers\HomeController.vb`

```
<LogActionFilter()> _
Public Class HomeController
     Inherits System.Web.Mvc.Controller

     Function Index()
          Return View()
     End Function

     Function About()
          Return View()
     End Function

            End Class
```

Summary

In this tutorial, you were introduced to ASP.NET MVC action filters. You learned about the four different types of filters: authorization filters, action filters, result filters, and exception filters. You also learned about the base `ActionFilterAttribute` class.

Finally, you learned how to implement a simple action filter. We created a Log action filter that logs the stages of processing a controller action to the Visual Studio Output window.

Improving Performance with Output Caching (VB)

4/10/2020 • 9 minutes to read • Edit Online

by Microsoft

> In this tutorial, you learn how you can dramatically improve the performance of your ASP.NET MVC web applications by taking advantage of output caching. You learn how to cache the result returned from a controller action so that the same content does not need to be created each and every time a new user invokes the action.

The goal of this tutorial is to explain how you can dramatically improve the performance of an ASP.NET MVC application by taking advantage of the output cache. The output cache enables you to cache the content returned by a controller action. That way, the same content does not need to be generated each and every time the same controller action is invoked.

Imagine, for example, that your ASP.NET MVC application displays a list of database records in a view named Index. Normally, each and every time that a user invokes the controller action that returns the Index view, the set of database records must be retrieved from the database by executing a database query.

If, on the other hand, you take advantage of the output cache then you can avoid executing a database query every time any user invokes the same controller action. The view can be retrieved from the cache instead of being regenerated from the controller action. Caching enables you to avoid performing redundant work on the server.

Enabling Output Caching

You enable output caching by adding an <OutputCache> attribute to either an individual controller action or an entire controller class. For example, the controller in Listing 1 exposes an action named Index(). The output of the Index() action is cached for 10 seconds.

Listing 1 – Controllers\HomeController.vb

```
<HandleError()> _
Public Class HomeController
    Inherits System.Web.Mvc.Controller

    <OutputCache(Duration:=10, VaryByParam:="none")> _
    Function Index()
        Return View()
    End Function

End Class
```

In the Beta versions of ASP.NET MVC, output caching does not work for a URL like http://www.MySite.com/. Instead, you must enter a URL like http://www.MySite.com/Home/Index.

In Listing 1, the output of the Index() action is cached for 10 seconds. If you prefer, you can specify a much longer cache duration. For example, if you want to cache the output of a controller action for one day then you can specify a cache duration of 86400 seconds (60 seconds * 60 minutes * 24 hours).

There is no guarantee that content will be cached for the amount of time that you specify. When memory resources become low, the cache starts evicting content automatically.

The Home controller in Listing 1 returns the Index view in Listing 2. There is nothing special about this view. The Index view simply displays the current time (see Figure 1).

Listing 2 – Views\Home\Index.aspx

```
<%@ Page Language="VB" Inherits="System.Web.Mvc.ViewPage" %>
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-
transitional.dtd">
<html xmlns="http://www.w3.org/1999/xhtml" >
<head runat="server">
    <title></title>
</head>
<body>
    <div>

    The current time is: <%= DateTime.Now.ToString("T") %>

    </div>
</body>
</html>
```

Figure 1 – Cached Index view

If you invoke the Index() action multiple times by entering the URL /Home/Index in the address bar of your browser and hitting the Refresh/Reload button in your browser repeatedly, then the time displayed by the Index view won't change for 10 seconds. The same time is displayed because the view is cached.

It is important to understand that the same view is cached for everyone who visits your application. Anyone who invokes the Index() action will get the same cached version of the Index view. This means that the amount of work that the web server must perform to serve the Index view is dramatically reduced.

The view in Listing 2 happens to be doing something really simple. The view just displays the current time. However, you could just as easily cache a view that displays a set of database records. In that case, the set of database records would not need to be retrieved from the database each and every time the controller action that returns the view is invoked. Caching can reduce the amount of work that both your web server and database server must perform.

Don't use the page <%@ OutputCache %> directive in an MVC view. This directive is bleeding over from the Web Forms world and should not be used in an ASP.NET MVC application.

Where Content is Cached

By default, when you use the <OutputCache> attribute, content is cached in three locations: the web server, any proxy servers, and the web browser. You can control exactly where content is cached by modifying the Location property of the <OutputCache> attribute.

You can set the Location property to any one of the following values:

- Any
- Client

· Downstream

· Server

· None

· ServerAndClient

By default, the Location property has the value Any. However, there are situations in which you might want to cache only on the browser or only on the server. For example, if you are caching information that is personalized for each user then you should not cache the information on the server. If you are displaying different information to different users then you should cache the information only on the client.

For example, the controller in Listing 3 exposes an action named GetName() that returns the current user name. If Jack logs into the website and invokes the GetName() action then the action returns the string "Hi Jack". If, subsequently, Jill logs into the website and invokes the GetName() action then she also will get the string "Hi Jack". The string is cached on the web server for all users after Jack initially invokes the controller action.

Listing 3 – Controllers\BadUserController.vb

```
Public Class BadUserController
    Inherits System.Web.Mvc.Controller

    <OutputCache(Duration:=3600, VaryByParam:="none")> _
    Function Index()
        Return "Hi " & User.Identity.Name
    End Function

End Class
```

Most likely, the controller in Listing 3 does not work the way that you want. You don't want to display the message "Hi Jack" to Jill.

You should never cache personalized content in the server cache. However, you might want to cache the personalized content in the browser cache to improve performance. If you cache content in the browser, and a user invokes the same controller action multiple times, then the content can be retrieved from the browser cache instead of the server.

The modified controller in Listing 4 caches the output of the GetName() action. However, the content is cached only on the browser and not on the server. That way, when multiple users invoke the GetName() method, each person gets their own user name and not another person's user name.

Listing 4 – Controllers\UserController.vb

```
Public Class UserController
    Inherits System.Web.Mvc.Controller

    <OutputCache(Duration:=3600, VaryByParam:="none", Location:=OutputCacheLocation.Client, NoStore:=True)> _
    Function GetName()
        Return "Hi " & User.Identity.Name
    End Function

End Class
```

Notice that the <OutputCache> attribute in Listing 4 includes a Location property set to the value OutputCacheLocation.Client. The <OutputCache> attribute also includes a NoStore property. The NoStore property is used to inform proxy servers and browsers that they should not store a permanent copy of the cached content.

Varying the Output Cache

In some situations, you might want different cached versions of the very same content. Imagine, for example, that you are creating a master/detail page. The master page displays a list of movie titles. When you click a title, you get details for the selected movie.

If you cache the details page, then the details for the same movie will be displayed no matter which movie you click. The first movie selected by the first user will be displayed to all future users.

You can fix this problem by taking advantage of the VaryByParam property of the <OutputCache> attribute. This property enables you to create different cached versions of the very same content when a form parameter or query string parameter varies.

For example, the controller in Listing 5 exposes two actions named Master() and Details(). The Master() action returns a list of movie titles and the Details() action returns the details for the selected movie.

Listing 5 – Controllers\MoviesController.vb

```
Public Class MoviesController
    Inherits System.Web.Mvc.Controller

    Private _dataContext As MovieDataContext

    Public Sub New()
        _dataContext = New MovieDataContext()
    End Sub

    <OutputCache(Duration:=Integer.MaxValue, VaryByParam:="none")> _
    Public Function Master()
        ViewData.Model = (From m In _dataContext.Movies _
                          Select m).ToList()
        Return View()
    End Function

    <OutputCache(Duration:=Integer.MaxValue, VaryByParam:="id")> _
    Public Function Details(ByVal id As Integer)
        ViewData.Model = _dataContext.Movies.SingleOrDefault(Function(m) m.Id = id)
        Return View()
    End Function

End Class
```

The Master() action includes a VaryByParam property with the value "none". When the Master() action is invoked, the same cached version of the Master view is returned. Any form parameters or query string parameters are ignored (see Figure 2).

Figure 2 – The /Movies/Master view

Figure 3 – The /Movies/Details view

The Details() action includes a VaryByParam property with the value "Id". When different values of the Id parameter are passed to the controller action, different cached versions of the Details view are generated.

It is important to understand that using the VaryByParam property results in more caching and not less. A different cached version of the Details view is created for each different version of the Id parameter.

You can set the VaryByParam property to the following values:

> * = Create a different cached version whenever a form or query string parameter varies.
>
> none = Never create different cached versions
>
> Semicolon list of parameters = Create different cached versions whenever any of the form or query string parameters in the list varies

Creating a Cache Profile

As an alternative to configuring output cache properties by modifying properties of the <OutputCache> attribute, you can create a cache profile in the web configuration (web.config) file. Creating a cache profile in the web configuration file offers a couple of important advantages.

First, by configuring output caching in the web configuration file, you can control how controller actions cache content in one central location. You can create one cache profile and apply the profile to several controllers or controller actions.

Second, you can modify the web configuration file without recompiling your application. If you need to disable caching for an application that has already been deployed to production, then you can simply modify the cache profiles defined in the web configuration file. Any changes to the web configuration file will be detected automatically and applied.

For example, the <caching> web configuration section in Listing 6 defines a cache profile named Cache1Hour. The <caching> section must appear within the <system.web> section of a web configuration file.

Listing 6 – Caching section for web.config

```
<caching>
<outputCacheSettings>
    <outputCacheProfiles>
        <add name="Cache1Hour" duration="3600" varyByParam="none"/>
    </outputCacheProfiles>
</outputCacheSettings>
</caching>
```

The controller in Listing 7 illustrates how you can apply the Cache1Hour profile to a controller action with the <OutputCache> attribute.

Listing 7 – Controllers\ProfileController.vb

```
Public Class ProfileController
    Inherits System.Web.Mvc.Controller

    <OutputCache(CacheProfile:="Cache1Hour")> _
    Function Index()
        Return DateTime.Now.ToString("T")
    End Function

End Class
```

If you invoke the Index() action exposed by the controller in Listing 7 then the same time will be returned for 1 hour.

Summary

Output caching provides you with a very easy method of dramatically improving the performance of your ASP.NET MVC applications. In this tutorial, you learned how to use the <OutputCache> attribute to cache the output of controller actions. You also learned how to modify properties of the <OutputCache> attribute such as the Duration and VaryByParam properties to modify how content gets cached. Finally, you learned how to define cache profiles in the web configuration file.

Adding Dynamic Content to a Cached Page (VB)

4/10/2020 • 5 minutes to read • Edit Online

by Microsoft

Learn how to mix dynamic and cached content in the same page. Post-cache substitution enables you to display dynamic content, such as banner advertisements or news items, within a page that has been output cached.

By taking advantage of output caching, you can dramatically improve the performance of an ASP.NET MVC application. Instead of regenerating a page each and every time the page is requested, the page can be generated once and cached in memory for multiple users.

But there is a problem. What if you need to display dynamic content in the page? For example, imagine that you want to display a banner advertisement in the page. You don't want the banner advertisement to be cached so that every user sees the very same advertisement. You wouldn't make any money that way!

Fortunately, there is an easy solution. You can take advantage of a feature of the ASP.NET framework called *post-cache substitution*. Post-cache substitution enables you to substitute dynamic content in a page that has been cached in memory.

Normally, when you output cache a page by using the <OutputCache> attribute, the page is cached on both the server and the client (the web browser). When you use post-cache substitution, a page is cached only on the server.

Using Post-Cache Substitution

Using post-cache substitution requires two steps. First, you need to define a method that returns a string that represents the dynamic content that you want to display in the cached page. Next, you call the HttpResponse.WriteSubstitution() method to inject the dynamic content into the page.

Imagine, for example, that you want to randomly display different news items in a cached page. The class in Listing 1 exposes a single method, named RenderNews(), that randomly returns one news item from a list of three news items.

Listing 1 – Models\News.vb

```
Public Class News

    Shared Function RenderNews(ByVal context As HttpContext) As String
        Dim newsItems As New List(Of String)
        newsItems.Add("Gas prices go up!")
        newsItems.Add("Life discovered on Mars!")
        newsItems.Add("Moon disappears!")

        Dim rnd As New Random()
        Return newsItems(rnd.Next(newsItems.Count))
    End Function

End Class
```

To take advantage of post-cache substitution, you call the HttpResponse.WriteSubstitution() method. The WriteSubstitution() method sets up the code to replace a region of the cached page with dynamic content. The WriteSubstitution() method is used to display the random news item in the view in Listing 2.

Listing 2 – Views\Home\Index.aspx

```
<%@ Page Language="VB" Inherits="System.Web.Mvc.ViewPage" %>
<%@ Import Namespace="MvcApplication1" %>
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-
transitional.dtd">
<html xmlns="http://www.w3.org/1999/xhtml" >
<head id="Head1" runat="server">
    <title>Index</title>
</head>
<body>
    <div>

    <% Response.WriteSubstitution(AddressOf News.RenderNews)%>

    <hr />

    The content of this page is output cached.
    <%= DateTime.Now %>

    </div>
</body>
</html>
```

The RenderNews method is passed to the WriteSubstitution() method. Notice that the RenderNews method is not called. Instead a reference to the method is passed to WriteSubstitution() with the help of the AddressOf operator.

The Index view is cached. The view is returned by the controller in Listing 3. Notice that the Index() action is decorated with an <OutputCache> attribute that causes the Index view to be cached for 60 seconds.

Listing 3 – Controllers\HomeController.vb

```
<HandleError()> _
Public Class HomeController
    Inherits System.Web.Mvc.Controller

    <OutputCache(Duration:=60, VaryByParam:="none")> _
    Function Index()
        Return View()
    End Function

End Class
```

Even though the Index view is cached, different random news items are displayed when you request the Index page. When you request the Index page, the time displayed by the page does not change for 60 seconds (see Figure 1). The fact that the time does not change proves that the page is cached. However, the content injected by the WriteSubstitution() method – the random news item – changes with each request .

Figure 1 – Injecting dynamic news items in a cached page

Using Post-Cache Substitution in Helper Methods

An easier way to take advantage of post-cache substitution is to encapsulate the call to the WriteSubstitution() method within a custom helper method. This approach is illustrated by the helper method in Listing 4.

Listing 4 – Helpers\AdHelper.vb

```
Imports System.Runtime.CompilerServices

Public Module AdHelper

    <Extension()> _
    Sub RenderBanner(ByVal helper As HtmlHelper)
        Dim context = helper.ViewContext.HttpContext
        context.Response.WriteSubstitution(AddressOf RenderBannerInternal)
    End Sub

    Private Function RenderBannerInternal(ByVal context As HttpContext) As String
        Dim ads As New List(Of String)
        ads.Add("/ads/banner1.gif")
        ads.Add("/ads/banner2.gif")
        ads.Add("/ads/banner3.gif")

        Dim rnd As New Random()
        Dim ad = ads(rnd.Next(ads.Count))
        Return String.Format("<img src='{0}' />", ad)
    End Function

End Module
```

Listing 4 contains a Visual Basic module that exposes two methods: RenderBanner() and RenderBannerInternal(). The RenderBanner() method represents the actual helper method. This method extends the standard ASP.NET MVC HtmlHelper class so that you can call Html.RenderBanner() in a view just like any other helper method.

The RenderBanner() method calls the HttpResponse.WriteSubstitution() method passing the RenderBannerInternal() method to the WriteSubstitution() method.

The RenderBannerInternal() method is a private method. This method won't be exposed as a helper method. The RenderBannerInternal() method randomly returns one banner advertisement image from a list of three banner advertisement images.

The modified Index view in Listing 5 illustrates how you can use the RenderBanner() helper method. Notice that an additional <%@ Import %> directive is included at the top of the view to import the MvcApplication1.Helpers namespace. If you neglect to import this namespace, then the RenderBanner() method won't appear as a method on the Html property.

Listing 5 – Views\Home\Index.aspx (with RenderBanner() method)

```
<%@ Page Language="VB" Inherits="System.Web.Mvc.ViewPage" %>
<%@ Import Namespace="MvcApplication1" %>
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Transitional//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-
transitional.dtd">
<html xmlns="http://www.w3.org/1999/xhtml" >
<head id="Head1" runat="server">
    <title>Index</title>
</head>
<body>
    <div>

    <% Response.WriteSubstitution(AddressOf News.RenderNews)%>

    <hr />

    <% Html.RenderBanner()%>

    <hr />

    The content of this page is output cached.
    <%= DateTime.Now %>

    </div>
</body>
</html>
```

When you request the page rendered by the view in Listing 5, a different banner advertisement is displayed with each request (see Figure 2). The page is cached, but the banner advertisement is injected dynamically by the RenderBanner() helper method.

Figure 2 – The Index view displaying a random banner advertisement

Summary

This tutorial explained how you can dynamically update content in a cached page. You learned how to use the HttpResponse.WriteSubstitution() method to enable dynamic content to be injected in a cached page. You also learned how to encapsulate the call to the WriteSubstitution() method within an HTML helper method.

Take advantage of caching whenever possible – it can have a dramatic impact on the performance of your web applications. As explained in this tutorial, you can take advantage of caching even when you need to display dynamic content in your pages.

Creating a Controller (VB)

2/20/2020 • 3 minutes to read • Edit Online

by Stephen Walther

In this tutorial, Stephen Walther demonstrates how you can add a controller to an ASP.NET MVC application.

The goal of this tutorial is to explain how you can create new ASP.NET MVC controllers. You learn how to create controllers both by using the Visual Studio Add Controller menu option and by creating a class file by hand.

Using the Add Controller Menu Option

The easiest way to create a new controller is to right-click the Controllers folder in the Visual Studio Solution Explorer window and select the **Add, Controller** menu option (see Figure 1). Selecting this menu option opens the **Add Controller** dialog (see Figure 2).

Figure 01: Adding a new controller(Click to view full-size image)

Figure 02: The Add Controller dialog (Click to view full-size image)

Notice that the first part of the controller name is highlighted in the **Add Controller** dialog. Every controller name must end with the suffix *Controller*. For example, you can create a controller named *ProductController* but not a controller named *Product*.

If you create a controller that is missing the *Controller* suffix then you won't be able to invoke the controller. Don't do this -- I've wasted countless hours of my life after making this mistake.

Listing 1 - Controllers\ProductController.vb

```
Public Class ProductController
    Inherits System.Web.Mvc.Controller

    '
    ' GET: /Product/

    Function Index() As ActionResult
        Return View()
    End Function

End Class
```

You should always create controllers in the Controllers folder. Otherwise, you'll be violating the conventions of ASP.NET MVC and other developers will have a more difficult time understanding your application.

Scaffolding Action Methods

When you create a controller, you have the option to generate Create, Update, and Details action methods automatically (see Figure 3). If you select this option then the controller class in Listing 2 is generated.

Figure 03: Creating action methods automatically (Click to view full-size image)

Listing 2 - Controllers\CustomerController.vb

```
Public Class CustomerController
    Inherits System.Web.Mvc.Controller

    '
    ' GET: /Customer/

    Function Index() As ActionResult
        Return View()
    End Function

    '
    ' GET: /Customer/Details/5

    Function Details(ByVal id As Integer) As ActionResult
        Return View()
    End Function

    '
    ' GET: /Customer/Create

    Function Create() As ActionResult
        Return View()
    End Function

    '
    ' POST: /Customer/Create

    <AcceptVerbs(HttpVerbs.Post)> _
    Function Create(ByVal collection As FormCollection) As ActionResult
        Try
            ' TODO: Add insert logic here
            Return RedirectToAction("Index")
        Catch
            Return View()
        End Try
    End Function

    '
    ' GET: /Customer/Edit/5

    Function Edit(ByVal id As Integer) As ActionResult
        Return View()
    End Function

    '
    ' POST: /Customer/Edit/5

    <AcceptVerbs(HttpVerbs.Post)> _
    Function Edit(ByVal id As Integer, ByVal collection As FormCollection) As ActionResult
        Try
            ' TODO: Add update logic here

            Return RedirectToAction("Index")
        Catch
            Return View()
        End Try
    End Function
End Class
```

These generated methods are stub methods. You must add the actual logic for creating, updating, and showing details for a customer yourself. But, the stub methods provide you with a nice starting point.

Creating a Controller Class

The ASP.NET MVC controller is just a class. If you prefer, you can ignore the convenient Visual Studio controller scaffolding and create a controller class by hand. Follow these steps:

1. Right-click the Controllers folder and select the menu option **Add, New Item** and select the **Class** template (see Figure 4).
2. Name the new class PersonController.vb and click the **Add** button.
3. Modify the resulting class file so that the class inherits from the base System.Web.Mvc.Controller class (see Listing 3).

Figure 04: Creating a new class(Click to view full-size image)

Listing 3 - Controllers\PersonController.vb

```
Public Class PersonController
    inherits Controller

    Function Index AS String
        Return "Hello World!"
    End Function

End Class
```

The controller in Listing 3 exposes one action named Index() that returns the string "Hello World!". You can invoke this controller action by running your application and requesting a URL like the following:

```
http://localhost:40071/Person
```

NOTE

The ASP.NET Development Server uses a random port number (for example, 40071). When entering a URL to invoke a controller, you'll need to supply the right port number. You can determine the port number by hovering your mouse over the icon for the ASP.NET Development Server in the Windows Notification Area (bottom-right of your screen).

Creating an Action (VB)

4/10/2020 • 2 minutes to read • Edit Online

by Microsoft

> Learn how to add a new action to an ASP.NET MVC controller. Learn about the requirements for a method to be an action.

The goal of this tutorial is to explain how you can create a new controller action. You learn about the requirements of an action method. You also learn how to prevent a method from being exposed as an action.

Adding an Action to a Controller

You add a new action to a controller by adding a new method to the controller. For example, the controller in Listing 1 contains an action named Index() and an action named SayHello(). Both methods are exposed as actions.

Listing 1 - Controllers\HomeController.vb

```
<HandleError()> _
Public Class HomeController
    Inherits System.Web.Mvc.Controller

    Function Index() As ActionResult
        Return View()
    End Function

    Function SayHello() As String
        Return "Hello!"
    End Function
End Class
```

In order to be exposed to the universe as an action, a method must meet certain requirements:

- The method must be public.
- The method cannot be a static method.
- The method cannot be an extension method.
- The method cannot be a constructor, getter, or setter.
- The method cannot have open generic types.
- The method is not a method of the controller base class.
- The method cannot contain **ref** or **out** parameters.

Notice that there are no restrictions on the return type of a controller action. A controller action can return a string, a DateTime, an instance of the Random class, or void. The ASP.NET MVC framework will convert any return type that is not an action result into a string and render the string to the browser.

When you add any method that does not violate these requirements to a controller, the method is exposed as a controller action. Be careful here. A controller action can be invoked by anyone connected to the Internet. Do not, for example, create a DeleteMyWebsite() controller action.

Preventing a Public Method from Being Invoked

If you need to create a public method in a controller class and you don't want to expose the method as a controller

action then you can prevent the method from being invoked by using the <NonAction> attribute. For example, the controller in Listing 2 contains a public method named CompanySecrets() that is decorated with the <NonAction> attribute.

Listing 2 - Controllers\WorkController.vb

```
Public Class WorkController
    Inherits System.Web.Mvc.Controller

     _
    Function CompanySecrets() As String
        Return "This information is secret."
    End Function

End Class
```

If you attempt to invoke the CompanySecrets() controller action by typing /Work/CompanySecrets into the address bar of your browser then you'll get the error message in Figure 1.

Figure 01: Invoking a NonAction method(Click to view full-size image)

ASP.NET MVC Controller Overview (C#)

2/20/2020 • 5 minutes to read • Edit Online

by Stephen Walther

> In this tutorial, Stephen Walther introduces you to ASP.NET MVC controllers. You learn how to create new controllers and return different types of action results.

This tutorial explores the topic of ASP.NET MVC controllers, controller actions, and action results. After you complete this tutorial, you will understand how controllers are used to control the way a visitor interacts with an ASP.NET MVC website.

Understanding Controllers

MVC controllers are responsible for responding to requests made against an ASP.NET MVC website. Each browser request is mapped to a particular controller. For example, imagine that you enter the following URL into the address bar of your browser:

```
http://localhost/Product/Index/3
```

In this case, a controller named ProductController is invoked. The ProductController is responsible for generating the response to the browser request. For example, the controller might return a particular view back to the browser or the controller might redirect the user to another controller.

Listing 1 contains a simple controller named ProductController.

Listing1 - Controllers\ProductController.cs

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using System.Web.Mvc;
using System.Web.Mvc.Ajax;

namespace MvcApplication1.Controllers
{
    public class ProductController : Controller
    {
        //
        // GET: /Products/

        public ActionResult Index()
        {
            // Add action logic here
            return View();
        }
    }
}
```

As you can see from Listing 1, a controller is just a class (a Visual Basic .NET or C# class). A controller is a class that derives from the base System.Web.Mvc.Controller class. Because a controller inherits from this base class, a controller inherits several useful methods for free (We discuss these methods in a moment).

Understanding Controller Actions

A controller exposes controller actions. An action is a method on a controller that gets called when you enter a particular URL in your browser address bar. For example, imagine that you make a request for the following URL:

```
http://localhost/Product/Index/3
```

In this case, the Index() method is called on the ProductController class. The Index() method is an example of a controller action.

A controller action must be a public method of a controller class. C# methods, by default, are private methods. Realize that any public method that you add to a controller class is exposed as a controller action automatically (You must be careful about this since a controller action can be invoked by anyone in the universe simply by typing the right URL into a browser address bar).

There are some additional requirements that must be satisfied by a controller action. A method used as a controller action cannot be overloaded. Furthermore, a controller action cannot be a static method. Other than that, you can use just about any method as a controller action.

Understanding Action Results

A controller action returns something called an *action result*. An action result is what a controller action returns in response to a browser request.

The ASP.NET MVC framework supports several types of action results including:

1. ViewResult - Represents HTML and markup.
2. EmptyResult - Represents no result.
3. RedirectResult - Represents a redirection to a new URL.
4. JsonResult - Represents a JavaScript Object Notation result that can be used in an AJAX application.
5. JavaScriptResult - Represents a JavaScript script.
6. ContentResult - Represents a text result.
7. FileContentResult - Represents a downloadable file (with the binary content).
8. FilePathResult - Represents a downloadable file (with a path).
9. FileStreamResult - Represents a downloadable file (with a file stream).

All of these action results inherit from the base ActionResult class.

In most cases, a controller action returns a ViewResult. For example, the Index controller action in Listing 2 returns a ViewResult.

Listing 2 - Controllers\BookController.cs

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using System.Web.Mvc;
using System.Web.Mvc.Ajax;

namespace MvcApplication1.Controllers
{
    public class BookController : Controller
    {
        public ActionResult Index()
        {
            // Add action logic here
            return View();
        }
    }
}
```

When an action returns a ViewResult, HTML is returned to the browser. The Index() method in Listing 2 returns a view named Index to the browser.

Notice that the Index() action in Listing 2 does not return a ViewResult(). Instead, the View() method of the Controller base class is called. Normally, you do not return an action result directly. Instead, you call one of the following methods of the Controller base class:

1. View - Returns a ViewResult action result.
2. Redirect - Returns a RedirectResult action result.
3. RedirectToAction - Returns a RedirectToRouteResult action result.
4. RedirectToRoute - Returns a RedirectToRouteResult action result.
5. Json - Returns a JsonResult action result.
6. JavaScriptResult - Returns a JavaScriptResult.
7. Content - Returns a ContentResult action result.
8. File - Returns a FileContentResult, FilePathResult, or FileStreamResult depending on the parameters passed to the method.

So, if you want to return a View to the browser, you call the View() method. If you want to redirect the user from one controller action to another, you call the RedirectToAction() method. For example, the Details() action in Listing 3 either displays a view or redirects the user to the Index() action depending on whether the Id parameter has a value.

Listing 3 - CustomerController.cs

```
using System.Web.Mvc;

namespace MvcApplication1.Controllers
{
    public class CustomerController : Controller
    {
        public ActionResult Details(int? id)
        {
            if (!id.HasValue)
                return RedirectToAction("Index");

            return View();
        }

        public ActionResult Index()
        {
            return View();
        }

    }
}
```

The ContentResult action result is special. You can use the ContentResult action result to return an action result as plain text. For example, the Index() method in Listing 4 returns a message as plain text and not as HTML.

Listing 4 - Controllers\StatusController.cs

```
using System.Web.Mvc;

namespace MvcApplication1.Controllers
{
    public class StatusController : Controller
    {
        public ActionResult Index()
        {
            return Content("Hello World!");
        }
    }
}
```

When the StatusController.Index() action is invoked, a view is not returned. Instead, the raw text "Hello World!" is returned to the browser.

If a controller action returns a result that is not an action result - for example, a date or an integer - then the result is wrapped in a ContentResult automatically. For example, when the Index() action of the WorkController in Listing 5 is invoked, the date is returned as a ContentResult automatically.

Listing 5 - WorkController.cs

```
using System;
using System.Web.Mvc;

namespace MvcApplication1.Controllers
{
    public class WorkController : Controller
    {
        public DateTime Index()
        {
            return DateTime.Now;
        }
    }
}
```

The Index() action in Listing 5 returns a DateTime object. The ASP.NET MVC framework converts the DateTime object to a string and wraps the DateTime value in a ContentResult automatically. The browser receives the date and time as plain text.

Summary

The purpose of this tutorial was to introduce you to the concepts of ASP.NET MVC controllers, controller actions, and controller action results. In the first section, you learned how to add new controllers to an ASP.NET MVC project. Next, you learned how public methods of a controller are exposed to the universe as controller actions. Finally, we discussed the different types of action results that can be returned from a controller action. In particular, we discussed how to return a ViewResult, RedirectToActionResult, and ContentResult from a controller action.

Creating Custom Routes (C#)

4/10/2020 • 2 minutes to read • Edit Online

by Microsoft

> Learn how to add custom routes to an ASP.NET MVC application. In this tutorial, you learn how to modify the default route table in the Global.asax file.

In this tutorial, you learn how to add a custom route to an ASP.NET MVC application. You learn how to modify the default route table in the Global.asax file with a custom route.

For many simple ASP.NET MVC applications, the default route table will work just fine. However, you might discover that you have specialized routing needs. In that case, you can create a custom route.

Imagine, for example, that you are building a blog application. You might want to handle incoming requests that look like this:

/Archive/12-25-2009

When a user enters this request, you want to return the blog entry that corresponds to the date 12/25/2009. In order to handle this type of request, you need to create a custom route.

The Global.asax file in Listing 1 contains a new custom route, named Blog, which handles requests that look like /Archive/*entry date*.

Listing 1 - Global.asax (with custom route)

```
using System.Web.Mvc;
using System.Web.Routing;
namespace MvcApplication1
{
    public class MvcApplication : System.Web.HttpApplication
    {
        public static void RegisterRoutes(RouteCollection routes)
        {
            routes.IgnoreRoute("{resource}.axd/{*pathInfo}");
            routes.MapRoute(
                "Blog",                                           // Route name
                "Archive/{entryDate}",                            // URL with parameters
                new { controller = "Archive", action = "Entry" }  // Parameter defaults
            );
            routes.MapRoute(
                "Default",                                             // Route name
                "{controller}/{action}/{id}",                          // URL with parameters
                new { controller = "Home", action = "Index", id = "" }  // Parameter defaults
            );
        }
        protected void Application_Start()
        {
            RegisterRoutes(RouteTable.Routes);
        }
    }
}
```

The order of the routes that you add to the route table is important. Our new custom Blog route is added before the existing Default route. If you reversed the order, then the Default route always will get called instead of the custom route.

The custom Blog route matches any request that starts with /Archive/. So, it matches all of the following URLs:

- /Archive/12-25-2009
- /Archive/10-6-2004
- /Archive/apple

The custom route maps the incoming request to a controller named Archive and invokes the Entry() action. When the Entry() method is called, the entry date is passed as a parameter named entryDate.

You can use the Blog custom route with the controller in Listing 2.

Listing 2 - ArchiveController.cs

```
using System;
using System.Web.Mvc;
namespace MvcApplication1.Controllers
{
    public class ArchiveController : Controller
    {
        public string Entry(DateTime entryDate)
        {
            return "You requested the entry from " + entryDate.ToString();
        }
    }
}
```

Notice that the Entry() method in Listing 2 accepts a parameter of type DateTime. The MVC framework is smart enough to convert the entry date from the URL into a DateTime value automatically. If the entry date parameter from the URL cannot be converted to a DateTime, an error is raised (see Figure 1).

Figure 1 - Error from converting parameter

Figure 01: Error from converting parameter (Click to view full-size image)

Summary

The goal of this tutorial was to demonstrate how you can create a custom route. You learned how to add a custom route to the route table in the Global.asax file that represents blog entries. We discussed how to map requests for blog entries to a controller named ArchiveController and a controller action named Entry().

Creating a Route Constraint (C#)

2/20/2020 • 2 minutes to read • Edit Online

by Stephen Walther

> In this tutorial, Stephen Walther demonstrates how you can control how browser requests match routes by creating route constraints with regular expressions.

You use route constraints to restrict the browser requests that match a particular route. You can use a regular expression to specify a route constraint.

For example, imagine that you have defined the route in Listing 1 in your Global.asax file.

Listing 1 - Global.asax.cs

```
routes.MapRoute(
    "Product",
    "Product/{productId}",
    new {controller="Product", action="Details"}
);
```

Listing 1 contains a route named Product. You can use the Product route to map browser requests to the ProductController contained in Listing 2.

Listing 2 - Controllers\ProductController.cs

```
using System.Web.Mvc;
namespace MvcApplication1.Controllers
{
    public class ProductController : Controller
    {
        public ActionResult Details(int productId)
        {
            return View();
        }
    }
}
```

Notice that the Details() action exposed by the Product controller accepts a single parameter named productId. This parameter is an integer parameter.

The route defined in Listing 1 will match any of the following URLs:

- /Product/23
- /Product/7

Unfortunately, the route will also match the following URLs:

- /Product/blah
- /Product/apple

Because the Details() action expects an integer parameter, making a request that contains something other than an integer value will cause an error. For example, if you type the URL /Product/apple into your browser then you will get the error page in Figure 1.

Figure 01: Seeing a page explode (Click to view full-size image)

What you really want to do is only match URLs that contain a proper integer productId. You can use a constraint when defining a route to restrict the URLs that match the route. The modified Product route in Listing 3 contains a regular expression constraint that only matches integers.

Listing 3 - Global.asax.cs

```
routes.MapRoute(
    "Product",
    "Product/{productId}",
    new {controller="Product", action="Details"},
    new {productId = @"\d+" }
 );
```

The regular expression \d+ matches one or more integers. This constraint causes the Product route to match the following URLs:

- /Product/3
- /Product/8999

But not the following URLs:

- /Product/apple
- /Product
- These browser requests will be handled by another route or, if there are no matching routes, a *The resource could not be found* error will be returned.

Creating a Custom Route Constraint (C#)

2/20/2020 • 2 minutes to read • Edit Online

by Stephen Walther

> Stephen Walther demonstrates how you can create a custom route constraint. We implement a simple custom constraint that prevents a route from being matched when a browser request is made from a remote computer.

The goal of this tutorial is to demonstrate how you can create a custom route constraint. A custom route constraint enables you to prevent a route from being matched unless some custom condition is matched.

In this tutorial, we create a Localhost route constraint. The Localhost route constraint only matches requests made from the local computer. Remote requests from across the Internet are not matched.

You implement a custom route constraint by implementing the IRouteConstraint interface. This is an extremely simple interface which describes a single method:

```
bool Match(
    HttpContextBase httpContext,
    Route route,
    string parameterName,
    RouteValueDictionary values,
    RouteDirection routeDirection
)
```

The method returns a Boolean value. If you return false, the route associated with the constraint won't match the browser request.

The Localhost constraint is contained in Listing 1.

Listing 1 - LocalhostConstraint.cs

```
using System.Web;
using System.Web.Routing;
namespace MvcApplication1.Constraints
{
    public class LocalhostConstraint : IRouteConstraint
    {
        public bool Match
            (
                HttpContextBase httpContext,
                Route route,
                string parameterName,
                RouteValueDictionary values,
                RouteDirection routeDirection
            )
        {
            return httpContext.Request.IsLocal;
        }
    }
}
```

The constraint in Listing 1 takes advantage of the IsLocal property exposed by the HttpRequest class. This property returns true when the IP address of the request is either 127.0.0.1 or when the IP of the request is the same as the

server's IP address.

You use a custom constraint within a route defined in the Global.asax file. The Global.asax file in Listing 2 uses the Localhost constraint to prevent anyone from requesting an Admin page unless they make the request from the local server. For example, a request for /Admin/DeleteAll will fail when made from a remote server.

Listing 2 - Global.asax

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using System.Web.Mvc;
using System.Web.Routing;
using MvcApplication1.Constraints;
namespace MvcApplication1
{
    public class MvcApplication : System.Web.HttpApplication
    {
        public static void RegisterRoutes(RouteCollection routes)
        {
            routes.IgnoreRoute("{resource}.axd/{*pathInfo}");
            routes.MapRoute(
                "Admin",
                "Admin/{action}",
                new {controller="Admin"},
                new {isLocal=new LocalhostConstraint()}
            );
            //routes.MapRoute(
            //    "Default",                                          // Route name
            //    "{controller}/{action}/{id}",                       // URL with parameters
            //    new { controller = "Home", action = "Index", id = "" }  // Parameter defaults
            //);
        }
        protected void Application_Start()
        {
            RegisterRoutes(RouteTable.Routes);
        }
    }
}
```

The Localhost constraint is used in the definition of the Admin route. This route won't be matched by a remote browser request. Realize, however, that other routes defined in Global.asax might match the same request. It is important to understand that a constraint prevents a particular route from matching a request and not all routes defined in the Global.asax file.

Notice that the Default route has been commented out from the Global.asax file in Listing 2. If you include the Default route, then the Default route would match requests for the Admin controller. In that case, remote users could still invoke actions of the Admin controller even though their requests wouldn't match the Admin route.

ASP.NET MVC Controller Overview (VB)

2/20/2020 • 5 minutes to read • Edit Online

by Stephen Walther

> In this tutorial, Stephen Walther introduces you to ASP.NET MVC controllers. You learn how to create new controllers and return different types of action results.

This tutorial explores the topic of ASP.NET MVC controllers, controller actions, and action results. After you complete this tutorial, you will understand how controllers are used to control the way a visitor interacts with an ASP.NET MVC website.

Understanding Controllers

MVC controllers are responsible for responding to requests made against an ASP.NET MVC website. Each browser request is mapped to a particular controller. For example, imagine that you enter the following URL into the address bar of your browser:

```
http://localhost/Product/Index/3
```

In this case, a controller named ProductController is invoked. The ProductController is responsible for generating the response to the browser request. For example, the controller might return a particular view back to the browser or the controller might redirect the user to another controller.

Listing 1 contains a simple controller named ProductController.

Listing1 - Controllers\ProductController.vb

```
Public Class ProductController
    Inherits System.Web.Mvc.Controller

    '
    ' GET: /Products/

    Function Index()
        ' Add action logic here
        Return View()
    End Function

End Class
```

As you can see from Listing 1, a controller is just a class (a Visual Basic .NET or C# class). A controller is a class that derives from the base System.Web.Mvc.Controller class. Because a controller inherits from this base class, a controller inherits several useful methods for free (We discuss these methods in a moment).

Understanding Controller Actions

A controller exposes controller actions. An action is a method on a controller that gets called when you enter a particular URL in your browser address bar. For example, imagine that you make a request for the following URL:

```
http://localhost/Product/Index/3
```

In this case, the Index() method is called on the ProductController class. The Index() method is an example of a controller action.

A controller action must be a public method of a controller class. Visual Basic.NET methods, by default, are public methods. Realize that any public method that you add to a controller class is exposed as a controller action automatically (You must be careful about this since a controller action can be invoked by anyone in the universe simply by typing the right URL into a browser address bar).

There are some additional requirements that must be satisfied by a controller action. A method used as a controller action cannot be overloaded. Furthermore, a controller action cannot be a static method. Other than that, you can use just about any method as a controller action.

Understanding Action Results

A controller action returns something called an *action result*. An action result is what a controller action returns in response to a browser request.

The ASP.NET MVC framework supports several types of action results including:

1. ViewResult - Represents HTML and markup.
2. EmptyResult - Represents no result.
3. RedirectResult - Represents a redirection to a new URL.
4. JsonResult - Represents a JavaScript Object Notation result that can be used in an AJAX application.
5. JavaScriptResult - Represents a JavaScript script.
6. ContentResult - Represents a text result.
7. FileContentResult - Represents a downloadable file (with the binary content).
8. FilePathResult - Represents a downloadable file (with a path).
9. FileStreamResult - Represents a downloadable file (with a file stream).

All of these action results inherit from the base ActionResult class.

In most cases, a controller action returns a ViewResult. For example, the Index controller action in Listing 2 returns a ViewResult.

Listing 2 - Controllers\BookController.vb

```
Public Class BookController
    Inherits System.Web.Mvc.Controller

    Function Index()
        Return View()
    End Function

End Class
```

When an action returns a ViewResult, HTML is returned to the browser. The Index() method in Listing 2 returns a view named Index to the browser.

Notice that the Index() action in Listing 2 does not return a ViewResult(). Instead, the View() method of the Controller base class is called. Normally, you do not return an action result directly. Instead, you call one of the following methods of the Controller base class:

1. View - Returns a ViewResult action result.
2. Redirect - Returns a RedirectResult action result.
3. RedirectToAction - Returns a RedirectToRouteResult action result.
4. RedirectToRoute - Returns a RedirectToRouteResult action result.
5. Json - Returns a JsonResult action result.
6. JavaScriptResult - Returns a JavaScriptResult.

7. Content - Returns a ContentResult action result.
8. File - Returns a FileContentResult, FilePathResult, or FileStreamResult depending on the parameters passed to the method.

So, if you want to return a View to the browser, you call the View() method. If you want to redirect the user from one controller action to another, you call the RedirectToAction() method. For example, the Details() action in Listing 3 either displays a view or redirects the user to the Index() action depending on whether the Id parameter has a value.

Listing 3 - CustomerController.vb

```
Public Class CustomerController
    Inherits System.Web.Mvc.Controller

    Function Details(ByVal id As Integer?)
        If Not id.HasValue Then
            Return RedirectToAction("Index")
        End If

        Return View()
    End Function
    Function Index()
        Return View()
    End Function

End Class
```

The ContentResult action result is special. You can use the ContentResult action result to return an action result as plain text. For example, the Index() method in Listing 4 returns a message as plain text and not as HTML.

Listing 4 - Controllers\StatusController.vb

StatusController

System.Web.Mvc.Controller

```
Public Class StatusController
    Inherits System.Web.Mvc.Controller

    Function Index()
        Return Content("Hello World!")
    End Function

End Class
```

When the StatusController.Index() action is invoked, a view is not returned. Instead, the raw text "Hello World!" is returned to the browser.

If a controller action returns a result that is not an action result - for example, a date or an integer - then the result is wrapped in a ContentResult automatically. For example, when the Index() action of the WorkController in Listing 5 is invoked, the date is returned as a ContentResult automatically.

Listing 5 - WorkController.vb

```
Public Class WorkController
    Inherits System.Web.Mvc.Controller

    Function Index()
        Return DateTime.Now
    End Function

End Class
```

The Index() action in Listing 5 returns a DateTime object. The ASP.NET MVC framework converts the DateTime object to a string and wraps the DateTime value in a ContentResult automatically. The browser receives the date and time as plain text.

Summary

The purpose of this tutorial was to introduce you to the concepts of ASP.NET MVC controllers, controller actions, and controller action results. In the first section, you learned how to add new controllers to an ASP.NET MVC project. Next, you learned how public methods of a controller are exposed to the universe as controller actions. Finally, we discussed the different types of action results that can be returned from a controller action. In particular, we discussed how to return a ViewResult, RedirectToActionResult, and ContentResult from a controller action.

Creating Custom Routes (VB)

4/10/2020 • 2 minutes to read • Edit Online

by Microsoft

Learn how to add custom routes to an ASP.NET MVC application. In this tutorial, you learn how to modify the default route table in the Global.asax file.

In this tutorial, you learn how to add a custom route to an ASP.NET MVC application. You learn how to modify the default route table in the Global.asax file with a custom route.

In ASP.NET MVC applications, the default route table will work just fine. However, you might discover that you have specialized routing needs. In that case, you can create a custom route.

Imagine, for example, that you are building a blog application. You might want to handle incoming requests that look like this:

/Archive/12-25-2009

When a user enters this request, you want to return the blog entry that corresponds to the date 12/25/2009. In order to handle this type of request, you need to create a custom route.

The Global.asax file in Listing 1 contains a new custom route, named Blog, which handles requests that look like /Archive/*entry date*.

Listing 1 - Global.asax (with custom route)

```
Public Class MvcApplication
    Inherits System.Web.HttpApplication
    Shared Sub RegisterRoutes(ByVal routes As RouteCollection)
        routes.IgnoreRoute("{resource}.axd/{*pathInfo}")
        ' MapRoute takes the following parameters, in order:
        ' (1) Route name
        ' (2) URL with parameters
        ' (3) Parameter defaults
        routes.MapRoute( _
            "Blog", _
            "Archive/{entryDate}", _
            New With {.controller = "Archive", .action = "Entry"} _
        )
        routes.MapRoute( _
            "Default", _
            "{controller}/{action}/{id}", _
            New With {.controller = "Home", .action = "Index", .id = ""} _
        )
    End Sub
    Sub Application_Start()
        RegisterRoutes(RouteTable.Routes)
    End Sub
End Class
```

The order of the routes that you add to the route table is important. Our new custom Blog route is added before the existing Default route. If you reversed the order, then the Default route always will get called instead of the custom route.

The custom Blog route matches any request that starts with /Archive/. So, it matches all of the following URLs:

- /Archive/12-25-2009
- /Archive/10-6-2004
- /Archive/apple

The custom route maps the incoming request to a controller named Archive and invokes the Entry() action. When the Entry() method is called, the entry date is passed as a parameter named entryDate.

You can use the Blog custom route with the controller in Listing 2.

Listing 2 - ArchiveController.vb

```
Public Class ArchiveController
    Inherits System.Web.Mvc.Controller
    Function Entry(ByVal entryDate As DateTime)
        Return "You requested the entry from " & entryDate.ToString()
    End Function
End Class
```

Notice that the Entry() method in Listing 2 accepts a parameter of type DateTime. The MVC framework is smart enough to convert the entry date from the URL into a DateTime value automatically. If the entry date parameter from the URL cannot be converted to a DateTime, an error is raised (see Figure 1).

Figure 1 - Error from converting parameter

Figure 01: Error from converting parameter (Click to view full-size image)

Summary

The goal of this tutorial was to demonstrate how you can create a custom route. You learned how to add a custom route to the route table in the Global.asax file that represents blog entries. We discussed how to map requests for blog entries to a controller named ArchiveController and a controller action named Entry().

Creating a Route Constraint (VB)

2/20/2020 • 2 minutes to read • Edit Online

by Stephen Walther

> In this tutorial, Stephen Walther demonstrates how you can control how browser requests match routes by creating route constraints with regular expressions.

You use route constraints to restrict the browser requests that match a particular route. You can use a regular expression to specify a route constraint.

For example, imagine that you have defined the route in Listing 1 in your Global.asax file.

Listing 1 - Global.asax.vb

```
routes.MapRoute( _
    "Product", _
    "Product/{productId}", _
    New With {.controller = "Product", .action = "Details"} _
)
```

Listing 1 contains a route named Product. You can use the Product route to map browser requests to the ProductController contained in Listing 2.

Listing 2 - Controllers\ProductController.vb

```
Public Class ProductController
    Inherits System.Web.Mvc.Controller
    Function Details(ByVal productId As Integer) As ActionResult
        Return View()
    End Function
End Class
```

Notice that the Details() action exposed by the Product controller accepts a single parameter named productId. This parameter is an integer parameter.

The route defined in Listing 1 will match any of the following URLs:

- /Product/23
- /Product/7

Unfortunately, the route will also match the following URLs:

- /Product/blah
- /Product/apple

Because the Details() action expects an integer parameter, making a request that contains something other than an integer value will cause an error. For example, if you type the URL /Product/apple into your browser then you will get the error page in Figure 1.

Figure 01: Seeing a page explode (Click to view full-size image)

What you really want to do is only match URLs that contain a proper integer productId. You can use a constraint when defining a route to restrict the URLs that match the route. The modified Product route in Listing 3 contains a regular expression constraint that only matches integers.

Listing 3 - Global.asax.vb

```
routes.MapRoute( _
   "Product", _
   "Product/{productId}", _
   New With {.controller = "Product", .action = "Details"}, _
   New With {.productId = "\d+"} _
)
```

The regular expression \d+ matches one or more integers. This constraint causes the Product route to match the following URLs:

- /Product/3
- /Product/8999

But not the following URLs:

- /Product/apple
- /Product

These browser requests will be handled by another route or, if there are no matching routes, a *The resource could not be found* error will be returned.

Creating a Custom Route Constraint (VB)

2/20/2020 • 2 minutes to read • Edit Online

by Stephen Walther

> Stephen Walther demonstrates how you can create a custom route constraint. We implement a simple custom constraint that prevents a route from being matched when a browser request is made from a remote computer.

The goal of this tutorial is to demonstrate how you can create a custom route constraint. A custom route constraint enables you to prevent a route from being matched unless some custom condition is matched.

In this tutorial, we create a Localhost route constraint. The Localhost route constraint only matches requests made from the local computer. Remote requests from across the Internet are not matched.

You implement a custom route constraint by implementing the IRouteConstraint interface. This is an extremely simple interface which describes a single method:

```
Function Match ( _
    httpContext As HttpContextBase, _
    route As Route, _
    parameterName As String, _
    values As RouteValueDictionary, _
    routeDirection As RouteDirection _
) As Boolean
```

The method returns a Boolean value. If you return False, the route associated with the constraint won't match the browser request.

The Localhost constraint is contained in Listing 1.

Listing 1 - LocalhostConstraint.vb

```
Public Class LocalhostConstraint
    Implements IRouteConstraint
    Public Function Match( _
                ByVal httpContext As HttpContextBase, _
                ByVal route As Route, _
                ByVal parameterName As String, _
                ByVal values As RouteValueDictionary, _
                ByVal routeDirection As RouteDirection _
            ) As Boolean Implements IRouteConstraint.Match
        Return httpContext.Request.IsLocal
    End Function
End Class
```

The constraint in Listing 1 takes advantage of the IsLocal property exposed by the HttpRequest class. This property returns true when the IP address of the request is either 127.0.0.1 or when the IP of the request is the same as the server's IP address.

You use a custom constraint within a route defined in the Global.asax file. The Global.asax file in Listing 2 uses the Localhost constraint to prevent anyone from requesting an Admin page unless they make the request from the local server. For example, a request for /Admin/DeleteAll will fail when made from a remote server.

Listing 2 - Global.asax

```
Public Class MvcApplication
    Inherits System.Web.HttpApplication
    Shared Sub RegisterRoutes(ByVal routes As RouteCollection)
        routes.IgnoreRoute("{resource}.axd/{*pathInfo}")
        routes.MapRoute( _
            "Admin", _
            "Admin/{action}", _
            New With {.controller = "Admin"}, _
            New With {.isLocal = New LocalhostConstraint()} _
        )
        'routes.MapRoute( _
        '    "Default", _
        '    "{controller}/{action}/{id}", _
        '    New With {.controller = "Home", .action = "Index", .id = ""} _
        ')
    End Sub
    Sub Application_Start()
        RegisterRoutes(RouteTable.Routes)
    End Sub
End Class
```

The Localhost constraint is used in the definition of the Admin route. This route won't be matched by a remote browser request. Realize, however, that other routes defined in Global.asax might match the same request. It is important to understand that a constraint prevents a particular route from matching a request and not all routes defined in the Global.asax file.

Notice that the Default route has been commented out from the Global.asax file in Listing 2. If you include the Default route, then the Default route would match requests for the Admin controller. In that case, remote users could still invoke actions of the Admin controller even though their requests wouldn't match the Admin route.

In this tutorial you learn how to use ASP.NET MVC and routing with different versions of IIS.

- Using ASP.NET MVC with Different Versions of IIS (C#)
- Using ASP.NET MVC with Different Versions of IIS (VB)

Using ASP.NET MVC with Different Versions of IIS (C#)

4/10/2020 • 11 minutes to read • Edit Online

by Microsoft

> In this tutorial, you learn how to use ASP.NET MVC, and URL Routing, with different versions of Internet Information Services. You learn different strategies for using ASP.NET MVC with IIS 7.0 (classic mode), IIS 6.0, and earlier versions of IIS.

The ASP.NET MVC framework depends on ASP.NET Routing to route browser requests to controller actions. In order to take advantage of ASP.NET Routing, you might have to perform additional configuration steps on your web server. It all depends on the version of Internet Information Services (IIS) and the request processing mode for your application.

Here's a summary of the different versions of IIS:

- IIS 7.0 (integrated mode) - No special configuration necessary to use ASP.NET Routing.
- IIS 7.0 (classic mode) - You need to perform special configuration to use ASP.NET Routing.
- IIS 6.0 or below - You need to perform special configuration to use ASP.NET Routing.

The latest version of IIS is version 7.5 (on Win7). IIS 7 of IIS is included with Windows Server 2008 AND VISTA/SP1 and higher. You also can install IIS 7.0 on any version of the Vista operating system except Home Basic (see https://technet.microsoft.com/library/cc731179%28WS.10%29.aspx).

IIS 7.0 supports two modes for processing requests. You can use integrated mode or classic mode. You don't need to perform any special configuration steps when using IIS 7.0 in integrated mode. However, you do need to perform additional configuration when using IIS 7.0 in classic mode.

Microsoft Windows Server 2003 includes IIS 6.0. You cannot upgrade IIS 6.0 to IIS 7.0 when using the Windows Server 2003 operating system. You must perform additional configuration steps when using IIS 6.0.

Microsoft Windows XP Professional includes IIS 5.1. You must perform additional configuration steps when using IIS 5.1.

Finally, Microsoft Windows 2000 and Microsoft Windows 2000 Professional includes IIS 5.0. You must perform additional configuration steps when using IIS 5.0.

Integrated versus Classic Mode

IIS 7.0 can process requests using two different request processing modes: integrated and classic. Integrated mode provides better performance and more features. Classic mode is included for backwards compatibility with earlier versions of IIS.

The request processing mode is determined by the application pool. You can determine which processing mode is being used by a particular web application by determining the application pool associated with the application. Follow these steps:

1. Launch the Internet Information Services Manager
2. In the Connections window, select an application
3. In the Actions window, click the **Basic Settings** link to open the Edit Application dialog box (see Figure 1)

4. Take note of the Application pool selected.

By default, IIS is configured to support two application pools: **DefaultAppPool** and **Classic .NET AppPool**. If DefaultAppPool is selected, then your application is running in integrated request processing mode. If Classic .NET AppPool is selected, your application is running in classic request processing mode.

Figure 1: Detecting the request processing mode(Click to view full-size image)

Notice that you can modify the request processing mode within the Edit Application dialog box. Click the Select button and change the application pool associated with the application. Realize that there are compatibility issues when changing an ASP.NET application from classic to integrated mode. For more information, see the following articles:

- Upgrading ASP.NET 1.1 to IIS 7.0 on Windows Vista and Windows Server 2008 -- https://www.iis.net/learn/application-frameworks/building-and-running-aspnet-applications/upgrading-aspnet-11-to-iis-on-windows-vista-and-windows-server-2008
- ASP.NET Integration With IIS 7.0 - https://www.iis.net/learn/application-frameworks/building-and-running-aspnet-applications/aspnet-integration-with-iis

If an ASP.NET application is using the DefaultAppPool, then you don't need to perform any additional steps to get ASP.NET Routing (and therefore ASP.NET MVC) to work. However, if the ASP.NET application is configured to use the Classic .NET AppPool then keep reading, you have more work to do.

Using ASP.NET MVC with Older Versions of IIS

If you need to use ASP.NET MVC with an older version of IIS than IIS 7.0, or you need to use IIS 7.0 in classic mode, then you have two options. First, you can modify the route table to use file extensions. For example, instead of requesting a URL like /Store/Details, you would request a URL like /Store.aspx/Details.

The second option is to create something called a *wildcard script map*. A wildcard script map enables you to map every request into the ASP.NET framework.

If you don't have access to your web server (for example, your ASP.NET MVC application is being hosted by an Internet Service Provider) then you'll need to use the first option. If you don't want to modify the appearance of your URLs, and you have access to your web server, then you can use the second option.

We explore each option in detail in the following sections.

Adding Extensions to the Route Table

The easiest way to get ASP.NET Routing to work with older versions of IIS is to modify your route table in the Global.asax file. The default and unmodified Global.asax file in Listing 1 configures one route named the Default route.

Listing 1 - Global.asax (unmodified)

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using System.Web.Mvc;
using System.Web.Routing;

namespace MvcApplication1
{
    public class GlobalApplication : System.Web.HttpApplication
    {
        public static void RegisterRoutes(RouteCollection routes)
        {
            routes.IgnoreRoute("{resource}.axd/{*pathInfo}");

            routes.MapRoute(
                "Default",                                          // Route name
                "{controller}/{action}/{id}",                       // URL with parameters
                new { controller = "Home", action = "Index", id = "" }  // Parameter defaults
            );
        }

        protected void Application_Start()
        {
            RegisterRoutes(RouteTable.Routes);
        }
    }
}
```

The Default route configured in Listing 1 enables you to route URLs that look like this:

/Home/Index

/Product/Details/3

/Product

Unfortunately, older versions of IIS won't pass these requests to the ASP.NET framework. Therefore, these requests won't get routed to a controller. For example, if you make a browser request for the URL /Home/Index then you'll get the error page in Figure 2.

Figure 2: Receiving a 404 Not Found error(Click to view full-size image)

Older versions of IIS only map certain requests to the ASP.NET framework. The request must be for a URL with the

right file extension. For example, a request for /SomePage.aspx gets mapped to the ASP.NET framework. However, a request for /SomePage.htm does not.

Therefore, to get ASP.NET Routing to work, we must modify the Default route so that it includes a file extension that is mapped to the ASP.NET framework.

This is done using a script named `registermvc.wsf`. It was included with the ASP.NET MVC 1 release in `C:\Program Files\Microsoft ASP.NET\ASP.NET MVC\Scripts`, but as of ASP.NET 2 this script has been moved to the ASP.NET Futures, available at http://aspnet.codeplex.com/releases/view/39978.

Executing this script registers a new .mvc extension with IIS. After you register the .mvc extension, you can modify your routes in the Global.asax file so that the routes use the .mvc extension.

The modified Global.asax file in Listing 2 works with older versions of IIS.

Listing 2 - Global.asax (modified with extensions)

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using System.Web.Mvc;
using System.Web.Routing;

namespace MvcApplication1
{
    public class MvcApplication : System.Web.HttpApplication
    {
        public static void RegisterRoutes(RouteCollection routes)
        {
            routes.IgnoreRoute("{resource}.axd/{*pathInfo}");

            routes.MapRoute(
                "Default",
                "{controller}.mvc/{action}/{id}",
                new { action = "Index", id = "" }
              );

            routes.MapRoute(
              "Root",
              "",
              new { controller = "Home", action = "Index", id = "" }
            );
        }

        protected void Application_Start()
        {
            RegisterRoutes(RouteTable.Routes);
        }
    }
}
```

Important: remember to build your ASP.NET MVC Application again after changing the Global.asax file.

There are two important changes to the Global.asax file in Listing 2. There are now two routes defined in the Global.asax. The URL pattern for the Default route, the first route, now looks like:

{controller}.mvc/{action}/{id}

The addition of the .mvc extension changes the type of files that the ASP.NET Routing module intercepts. With this change, the ASP.NET MVC application now routes requests like the following:

/Home.mvc/Index/

/Product.mvc/Details/3

/Product.mvc/

The second route, the Root route, is new. This URL pattern for the Root route is an empty string. This route is necessary for matching requests made against the root of your application. For example, the Root route will match a request that looks like this:

http://www.YourApplication.com/

After making these modifications to your route table, you'll need to make sure that all of the links in your application are compatible with these new URL patterns. In other words, make sure that all of your links include the .mvc extension. If you use the Html.ActionLink() helper method to generate your links, then you should not need to make any changes.

Instead of using the registermvc.wcf script, you can add a new extension to IIS that is mapped to the ASP.NET framework by hand. When adding a new extension yourself, make sure that the checkbox labeled **Verify that file exists** is not checked.

Hosted Server

You don't always have access to your web server. For example, if you are hosting your ASP.NET MVC application using an Internet Hosting Provider, then you won't necessarily have access to IIS.

In that case, you should use one of the existing file extensions that are mapped to the ASP.NET framework. Examples of file extensions mapped to ASP.NET include the .aspx, .axd, and .ashx extensions.

For example, the modified Global.asax file in Listing 3 uses the .aspx extension instead of the .mvc extension.

Listing 3 - Global.asax (modified with .aspx extensions)

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using System.Web.Mvc;
using System.Web.Routing;

namespace MvcApplication1
{
    public class MvcApplication : System.Web.HttpApplication
    {
        public static void RegisterRoutes(RouteCollection routes)
        {
            routes.IgnoreRoute("{resource}.axd/{*pathInfo}");

            routes.MapRoute(
                "Default",
                "{controller}.aspx/{action}/{id}",
                new { action = "Index", id = "" }
              );

            routes.MapRoute(
              "Root",
              "",
              new { controller = "Home", action = "Index", id = "" }
            );
        }

        protected void Application_Start()
        {
            RegisterRoutes(RouteTable.Routes);
        }
    }
}
```

The Global.asax file in Listing 3 is exactly the same as the previous Global.asax file except for the fact that it uses the .aspx extension instead of the .mvc extension. You don't have to perform any setup on your remote web server to use the .aspx extension.

Creating a Wildcard Script Map

If you don't want to modify the URLs for your ASP.NET MVC application, and you have access to your web server, then you have an additional option. You can create a wildcard script map that maps all requests to the web server to the ASP.NET framework. That way, you can use the default ASP.NET MVC route table with IIS 7.0 (in classic mode) or IIS 6.0.

Be aware that this option causes IIS to intercept every request made against the web server. This includes requests for images, classic ASP pages, and HTML pages. Therefore, enabling a wildcard script map to ASP.NET does have performance implications.

Here's how you enable a wildcard script map for IIS 7.0:

1. Select your application in the Connections window
2. Make sure that the **Features** view is selected
3. Double-click the **Handler Mappings** button
4. Click the **Add Wildcard Script Map** link (see Figure 3)
5. Enter the path to the aspnet_isapi.dll file (You can copy this path from the PageHandlerFactory script map)
6. Enter the name MVC
7. Click the **OK** button

Figure 3: Creating a wildcard script map with IIS 7.0(Click to view full-size image)

Follow these steps to create a wildcard script map with IIS 6.0:

1. Right-click a website and select Properties
2. Select the **Home Directory** tab
3. Click the **Configuration** button
4. Select the **Mappings** tab
5. Click the **Insert** button (see Figure 4)
6. Paste the path to the aspnet_isapi.dll into the Executable field (you can copy this path from the script map for .aspx files)
7. Uncheck the checkbox labeled **Verify that file exists**
8. Click the **OK** button

Figure 4: Creating a wildcard script map with IIS 6.0(Click to view full-size image)

After you enable wildcard script maps, you need to modify the route table in the Global.asax file so that it includes a Root route. Otherwise, you'll get the error page in Figure 5 when you make a request for the root page of your application. You can use the modified Global.asax file in Listing 4.

Figure 5: Missing Root route error(Click to view full-size image)

Listing 4 - Global.asax (modified with Root route)

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using System.Web.Mvc;
using System.Web.Routing;

namespace MvcApplication1
{

    public class MvcApplication : System.Web.HttpApplication
    {
        public static void RegisterRoutes(RouteCollection routes)
        {
            routes.IgnoreRoute("{resource}.axd/{*pathInfo}");

            routes.MapRoute(
                "Default",
                "{controller}/{action}/{id}",
                new { action = "Index", id = "" }
              );

            routes.MapRoute(
              "Root",
              "",
              new { controller = "Home", action = "Index", id = "" }
            );

        }

        protected void Application_Start()
        {
            RegisterRoutes(RouteTable.Routes);
        }
    }
}
```

After you enable a wildcard script map for either IIS 7.0 or IIS 6.0, you can make requests that work with the default route table that look like this:

/

/Home/Index

/Product/Details/3

/Product

Summary

The goal of this tutorial was to explain how you can use ASP.NET MVC when using an older version of IIS (or IIS 7.0 in classic mode). We discussed two methods of getting ASP.NET Routing to work with older versions of IIS: Modify the default route table or create a wildcard script map.

The first option requires you to modify the URLs used in your ASP.NET MVC application. One very significant advantage of this first option is that you do not need access to a web server in order to modify the route table. That means that you can use this first option even when hosting your ASP.NET MVC application with an Internet hosting company.

The second option is to create a wildcard script map. The advantage of this second option is that you do not need to modify your URLs. The disadvantage of this second option is that it can impact the performance of your ASP.NET MVC application.

Using ASP.NET MVC with Different Versions of IIS (VB)

4/10/2020 • 11 minutes to read • Edit Online

by Microsoft

> In this tutorial, you learn how to use ASP.NET MVC, and URL Routing, with different versions of Internet Information Services. You learn different strategies for using ASP.NET MVC with IIS 7.0 (classic mode), IIS 6.0, and earlier versions of IIS.

The ASP.NET MVC framework depends on ASP.NET Routing to route browser requests to controller actions. In order to take advantage of ASP.NET Routing, you might have to perform additional configuration steps on your web server. It all depends on the version of Internet Information Services (IIS) and the request processing mode for your application.

Here's a summary of the different versions of IIS:

- IIS 7.0 (integrated mode) - No special configuration necessary to use ASP.NET Routing.
- IIS 7.0 (classic mode) - You need to perform special configuration to use ASP.NET Routing.
- IIS 6.0 or below - You need to perform special configuration to use ASP.NET Routing.

The latest version of IIS is version 7.5 (on Win7). IIS 7 of IIS is included with Windows Server 2008 AND VISTA/SP1 and higher. You also can install IIS 7.0 on any version of the Vista operating system except Home Basic (see https://technet.microsoft.com/library/cc731179%28WS.10%29.aspx).

IIS 7.0 supports two modes for processing requests. You can use integrated mode or classic mode. You don't need to perform any special configuration steps when using IIS 7.0 in integrated mode. However, you do need to perform additional configuration when using IIS 7.0 in classic mode.

Microsoft Windows Server 2003 includes IIS 6.0. You cannot upgrade IIS 6.0 to IIS 7.0 when using the Windows Server 2003 operating system. You must perform additional configuration steps when using IIS 6.0.

Microsoft Windows XP Professional includes IIS 5.1. You must perform additional configuration steps when using IIS 5.1.

Finally, Microsoft Windows 2000 and Microsoft Windows 2000 Professional includes IIS 5.0. You must perform additional configuration steps when using IIS 5.0.

Integrated versus Classic Mode

IIS 7.0 can process requests using two different request processing modes: integrated and classic. Integrated mode provides better performance and more features. Classic mode is included for backwards compatibility with earlier versions of IIS.

The request processing mode is determined by the application pool. You can determine which processing mode is being used by a particular web application by determining the application pool associated with the application. Follow these steps:

1. Launch the Internet Information Services Manager
2. In the Connections window, select an application
3. In the Actions window, click the **Basic Settings** link to open the Edit Application dialog box (see Figure 1)

4. Take note of the Application pool selected.

By default, IIS is configured to support two application pools: **DefaultAppPool** and **Classic .NET AppPool**. If DefaultAppPool is selected, then your application is running in integrated request processing mode. If Classic .NET AppPool is selected, your application is running in classic request processing mode.

Figure 1: Detecting the request processing mode(Click to view full-size image)

Notice that you can modify the request processing mode within the Edit Application dialog box. Click the Select button and change the application pool associated with the application. Realize that there are compatibility issues when changing an ASP.NET application from classic to integrated mode. For more information, see the following articles:

- Upgrading ASP.NET 1.1 to IIS 7.0 on Windows Vista and Windows Server 2008 -- https://www.iis.net/learn/application-frameworks/building-and-running-aspnet-applications/upgrading-aspnet-11-to-iis-on-windows-vista-and-windows-server-2008
- ASP.NET Integration With IIS 7.0 - https://www.iis.net/learn/application-frameworks/building-and-running-aspnet-applications/aspnet-integration-with-iis

If an ASP.NET application is using the DefaultAppPool, then you don't need to perform any additional steps to get ASP.NET Routing (and therefore ASP.NET MVC) to work. However, if the ASP.NET application is configured to use the Classic .NET AppPool then keep reading, you have more work to do.

Using ASP.NET MVC with Older Versions of IIS

If you need to use ASP.NET MVC with an older version of IIS than IIS 7.0, or you need to use IIS 7.0 in classic mode, then you have two options. First, you can modify the route table to use file extensions. For example, instead of requesting a URL like /Store/Details, you would request a URL like /Store.aspx/Details.

The second option is to create something called a *wildcard script map*. A wildcard script map enables you to map every request into the ASP.NET framework.

If you don't have access to your web server (for example, your ASP.NET MVC application is being hosted by an Internet Service Provider) then you'll need to use the first option. If you don't want to modify the appearance of your URLs, and you have access to your web server, then you can use the second option.

We explore each option in detail in the following sections.

Adding Extensions to the Route Table

The easiest way to get ASP.NET Routing to work with older versions of IIS is to modify your route table in the Global.asax file. The default and unmodified Global.asax file in Listing 1 configures one route named the Default route.

Listing 1 - Global.asax (unmodified)

```
Public Class MvcApplication

        Inherits System.Web.HttpApplication

        Shared Sub RegisterRoutes(ByVal routes As RouteCollection)

            routes.IgnoreRoute("{resource}.axd/{*pathInfo}")

            ' MapRoute takes the following parameters, in order:

            ' (1) Route name

            ' (2) URL with parameters

            ' (3) Parameter defaults

            routes.MapRoute( _

                "Default", _

                "{controller}/{action}/{id}", _

                New With {.controller = "Home", .action = "Index", .id = ""} _

            )

        End Sub

        Sub Application_Start()

            RegisterRoutes(RouteTable.Routes)

        End Sub

    End Class
```

The Default route configured in Listing 1 enables you to route URLs that look like this:

/Home/Index

/Product/Details/3

/Product

Unfortunately, older versions of IIS won't pass these requests to the ASP.NET framework. Therefore, these requests won't get routed to a controller. For example, if you make a browser request for the URL /Home/Index then you'll get the error page in Figure 2.

Figure 2: Receiving a 404 Not Found error(Click to view full-size image)

Older versions of IIS only map certain requests to the ASP.NET framework. The request must be for a URL with the right file extension. For example, a request for /SomePage.aspx gets mapped to the ASP.NET framework. However, a request for /SomePage.htm does not.

Therefore, to get ASP.NET Routing to work, we must modify the Default route so that it includes a file extension that is mapped to the ASP.NET framework.

This is done using a script named `registermvc.wsf`. It was included with the ASP.NET MVC 1 release in `C:\Program Files\Microsoft ASP.NET\ASP.NET MVC\Scripts`, but as of ASP.NET 2 this script has been moved to the ASP.NET Futures, available at http://aspnet.codeplex.com/releases/view/39978.

Executing this script registers a new .mvc extension with IIS. After you register the .mvc extension, you can modify your routes in the Global.asax file so that the routes use the .mvc extension.

The modified Global.asax file in Listing 2 works with older versions of IIS.

Listing 2 - Global.asax (modified with extensions)

```
Public Class MvcApplication

        Inherits System.Web.HttpApplication

        Shared Sub RegisterRoutes(ByVal routes As RouteCollection)

            routes.IgnoreRoute("{resource}.axd/{*pathInfo}")

            ' MapRoute takes the following parameters, in order:

            ' (1) Route name

            ' (2) URL with parameters

            ' (3) Parameter defaults

            routes.MapRoute( _

                "Default", _

                "{controller}.mvc/{action}/{id}", _

                New With {.controller = "Home", .action = "Index", .id = ""} _

            )

            routes.MapRoute( _

                "Root", _

                "", _

                New With {.controller = "Home", .action = "Index", .id = ""} _

            )

        End Sub

        Sub Application_Start()

            RegisterRoutes(RouteTable.Routes)

        End Sub

    End Class
```

Important: remember to build your ASP.NET MVC Application again after changing the Global.asax file.

There are two important changes to the Global.asax file in Listing 2. There are now two routes defined in the Global.asax. The URL pattern for the Default route, the first route, now looks like:

{controller}.mvc/{action}/{id}

The addition of the .mvc extension changes the type of files that the ASP.NET Routing module intercepts. With this change, the ASP.NET MVC application now routes requests like the following:

/Home.mvc/Index/

/Product.mvc/Details/3

/Product.mvc/

The second route, the Root route, is new. This URL pattern for the Root route is an empty string. This route is necessary for matching requests made against the root of your application. For example, the Root route will match a request that looks like this:

http://www.YourApplication.com/

After making these modifications to your route table, you'll need to make sure that all of the links in your application are compatible with these new URL patterns. In other words, make sure that all of your links include the .mvc extension. If you use the Html.ActionLink() helper method to generate your links, then you should not need to make any changes.

Instead of using the registermvc.wcf script, you can add a new extension to IIS that is mapped to the ASP.NET framework by hand. When adding a new extension yourself, make sure that the checkbox labeled **Verify that file exists** is not checked.

Hosted Server

You don't always have access to your web server. For example, if you are hosting your ASP.NET MVC application using an Internet Hosting Provider, then you won't necessarily have access to IIS.

In that case, you should use one of the existing file extensions that are mapped to the ASP.NET framework. Examples of file extensions mapped to ASP.NET include the .aspx, .axd, and .ashx extensions.

For example, the modified Global.asax file in Listing 3 uses the .aspx extension instead of the .mvc extension.

Listing 3 - Global.asax (modified with .aspx extensions)

```
Public Class MvcApplication

        Inherits System.Web.HttpApplication

        Shared Sub RegisterRoutes(ByVal routes As RouteCollection)

            routes.IgnoreRoute("{resource}.axd/{*pathInfo}")

            ' MapRoute takes the following parameters, in order:

            ' (1) Route name

            ' (2) URL with parameters

            ' (3) Parameter defaults

            routes.MapRoute( _

                "Default", _

                "{controller}.aspx/{action}/{id}", _

                New With {.controller = "Home", .action = "Index", .id = ""} _

            )

            routes.MapRoute( _

                "Root", _

                "", _

                New With {.controller = "Home", .action = "Index", .id = ""} _

            )

        End Sub

        Sub Application_Start()

            RegisterRoutes(RouteTable.Routes)

        End Sub

    End Class
```

The Global.asax file in Listing 3 is exactly the same as the previous Global.asax file except for the fact that it uses the .aspx extension instead of the .mvc extension. You don't have to perform any setup on your remote web server to use the .aspx extension.

Creating a Wildcard Script Map

If you don't want to modify the URLs for your ASP.NET MVC application, and you have access to your web server, then you have an additional option. You can create a wildcard script map that maps all requests to the web server to the ASP.NET framework. That way, you can use the default ASP.NET MVC route table with IIS 7.0 (in classic mode) or IIS 6.0.

Be aware that this option causes IIS to intercept every request made against the web server. This includes requests for images, classic ASP pages, and HTML pages. Therefore, enabling a wildcard script map to ASP.NET does have performance implications.

Here's how you enable a wildcard script map for IIS 7.0:

1. Select your application in the Connections window
2. Make sure that the **Features** view is selected
3. Double-click the **Handler Mappings** button
4. Click the **Add Wildcard Script Map** link (see Figure 3)
5. Enter the path to the aspnet_isapi.dll file (You can copy this path from the PageHandlerFactory script map)
6. Enter the name MVC
7. Click the **OK** button

Figure 3: Creating a wildcard script map with IIS 7.0(Click to view full-size image)

Follow these steps to create a wildcard script map with IIS 6.0:

1. Right-click a website and select Properties
2. Select the **Home Directory** tab
3. Click the **Configuration** button
4. Select the **Mappings** tab
5. Click the **Insert** button (see Figure 4)
6. Paste the path to the aspnet_isapi.dll into the Executable field (you can copy this path from the script map for .aspx files)
7. Uncheck the checkbox labeled **Verify that file exists**
8. Click the **OK** button

Figure 4: Creating a wildcard script map with IIS 6.0(Click to view full-size image)

After you enable wildcard script maps, you need to modify the route table in the Global.asax file so that it includes a Root route. Otherwise, you'll get the error page in Figure 5 when you make a request for the root page of your application. You can use the modified Global.asax file in Listing 4.

Figure 5: Missing Root route error(Click to view full-size image)

Listing 4 - Global.asax (modified with Root route)

```
Public Class MvcApplication

        Inherits System.Web.HttpApplication

        Shared Sub RegisterRoutes(ByVal routes As RouteCollection)

            routes.IgnoreRoute("{resource}.axd/{*pathInfo}")

            ' MapRoute takes the following parameters, in order:

            ' (1) Route name

            ' (2) URL with parameters

            ' (3) Parameter defaults

            routes.MapRoute( _

                "Default", _

                "{controller}/{action}/{id}", _

                New With {.controller = "Home", .action = "Index", .id = ""} _

            )

            routes.MapRoute( _

                "Root", _

                "", _

                New With {.controller = "Home", .action = "Index", .id = ""} _

            )

        End Sub

        Sub Application_Start()

            RegisterRoutes(RouteTable.Routes)

        End Sub

    End Class
```

After you enable a wildcard script map for either IIS 7.0 or IIS 6.0, you can make requests that work with the default route table that look like this:

/

/Home/Index

/Product/Details/3

/Product

Summary

The goal of this tutorial was to explain how you can use ASP.NET MVC when using an older version of IIS (or IIS 7.0 in classic mode). We discussed two methods of getting ASP.NET Routing to work with older versions of IIS: Modify the default route table or create a wildcard script map.

The first option requires you to modify the URLs used in your ASP.NET MVC application. One very significant

advantage of this first option is that you do not need access to a web server in order to modify the route table. That means that you can use this first option even when hosting your ASP.NET MVC application with an Internet hosting company.

The second option is to create a wildcard script map. The advantage of this second option is that you do not need to modify your URLs. The disadvantage of this second option is that it can impact the performance of your ASP.NET MVC application.

by Microsoft

> Learn how to use the [Authorize] attribute to password protect particular pages in your MVC application. You learn how to use the Web Site Administration Tool to create and manage users and roles. You also learn how to configure where user account and role information is stored.

The goal of this tutorial is to explain how you can use Forms authentication to password protect the views in your ASP.NET MVC applications. You learn how to use the Web Site Administration Tool to create users and roles. You also learn how to prevent unauthorized users from invoking controller actions. Finally, you learn how to configure where user names and passwords are stored.

Using the Web Site Administration Tool

Before we do anything else, we should start by creating some users and roles. The easiest way to create new users and roles is to take advantage of the Visual Studio 2008 Web Site Administration Tool. You can launch this tool by selecting the menu option **Project, ASP.NET Configuration**. Alternatively, you can launch the Web Site Administration Tool by clicking the (somewhat scary) icon of the hammer hitting the world that appears at the top of the Solution Explorer window (see Figure 1).

Figure 1 – Launching the Web Site Administration Tool

Within the Web Site Administration Tool, you create new users and roles by selecting the Security tab. Click the **Create user** link to create a new user named Stephen (see Figure 2). Provide the Stephen user with any password that you want (for example, *secret*).

Figure 2 – Creating a new user

You create new roles by first enabling roles and defining one or more roles. Enable roles by clicking the **Enable roles** link. Next, create a role named *Administrators* by clicking the **Create or Manage roles** link (see Figure 3).

Figure 3 – Creating a new role

Finally, create a new user named Sally and associate Sally with the Administrators role by clicking the Create User link and selecting Administrators when creating Sally (see Figure 4).

Figure 4 – Adding a user to a role

When all is said and done, you should have two new users named Stephen and Sally. You should also have a new

role named Administrators. Sally is a member of the Administrators role and Stephen is not.

Requiring Authorization

You can require a user to be authenticated before the user invokes a controller action by adding the [Authorize] attribute to the action. You can apply the [Authorize] attribute to an individual controller action or you can apply this attribute to an entire controller class.

For example, the controller in Listing 1 exposes an action named CompanySecrets(). Because this action is decorated with the [Authorize] attribute, this action cannot be invoked unless a user is authenticated.

Listing 1 – Controllers\HomeController.cs

```
using System.Web.Mvc;

namespace MvcApplication1.Controllers
{
    [HandleError]
    public class HomeController : Controller
    {
        public ActionResult Index()
        {
            return View();
        }

        [Authorize]
        public ActionResult CompanySecrets()
        {
            return View();
        }
    }
}
```

If you invoke the CompanySecrets() action by entering the URL /Home/CompanySecrets in the address bar of your browser, and you are not an authenticated user, then you will be redirected to the Login view automatically (see Figure 5).

Figure 5 – The Login view

You can use the Login view to enter your user name and password. If you are not a registered user then you can click the **register** link to navigate to the Register view (see Figure 6). You can use the Register view to create a new user account.

Figure 6 – The Register view

After you successfully log in, you can see the CompanySecrets view (see Figure 7). By default, you will continue to be logged in until you close your browser window.

Figure 7 – The CompanySecrets view

Authorizing by User Name or User Role

You can use the [Authorize] attribute to restrict access to a controller action to a particular set of users or a particular set of user roles. For example, the modified Home controller in Listing 2 contains two new actions named StephenSecrets() and AdministratorSecrets().

Listing 2 – Controllers\HomeController.cs

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using System.Web.Mvc;
using System.Web.Mvc.Ajax;

namespace MvcApplication1.Controllers
{
    [HandleError]
    public class HomeController : Controller
    {
        public ActionResult Index()
        {
            return View();
        }

        [Authorize]
        public ActionResult CompanySecrets()
        {
            return View();
        }

        [Authorize(Users="Stephen")]
        public ActionResult StephenSecrets()
        {
            return View();
        }

        [Authorize(Roles = "Administrators")]
        public ActionResult AdministratorSecrets()
        {
            return View();
        }

    }
}
```

Only a user with the user name Stephen can invoke the StephenSecrets() action. All other users get redirected to the Login view. The Users property accepts a comma separated list of user account names.

Only users in the Administrators role can invoke the AdministratorSecrets() action. For example, because Sally is a member of the Administrators group, she can invoke the AdministratorSecrets() action. All other users get redirected to the Login view. The Roles property accepts a comma separated list of role names.

Configuring Authentication

At this point, you might be wondering where the user account and role information is being stored. By default, the information is stored in a (RANU) SQL Express database named ASPNETDB.mdf located in your MVC application's App_Data folder. This database is generated by the ASP.NET framework automatically when you start using membership.

In order to see the ASPNETDB.mdf database in the Solution Explorer window, you first need to select the menu option Project, Show All Files.

Using the default SQL Express database is fine when developing an application. Most likely, however, you won't want to use the default ASPNETDB.mdf database for a production application. In that case, you can change where user account information is stored by completing the following two steps:

1. Add the Application Services database objects to your production database - Change your application connection string to point to your production database

The first step is to add all of the necessary database objects (tables and stored procedures) to your production database. The easiest way to add these objects to a new database is to take advantage of the ASP.NET SQL Server Setup Wizard (see Figure 8). You can launch this tool by opening the Visual Studio 2008 Command Prompt from the Microsoft Visual Studio 2008 program group and executing the following command from the command prompt:

aspnet_regsql

Figure 8 – The ASP.NET SQL Server Setup Wizard

The ASP.NET SQL Server Setup Wizard enables you to select a SQL Server database on your network and install all of the database objects required by the ASP.NET application services. The database server is not required to be located on your local machine.

> **NOTE**
>
> If you don't want to use the ASP.NET SQL Server Setup Wizard, then you can find SQL scripts for adding the application services database objects in the following folder:
>
> C:\Windows\Microsoft.NET\Framework\v2.0.50727

After you create the necessary database objects, you need to modify the database connection used by your MVC application. Modify the ApplicationServices connection string in your web configuration (web.config) file so that it points to the production database. For example, the modified connection in Listing 3 points to a database named MyProductionDB (the original ApplicationServices connection string has been commented out).

Listing 3 – Web.config

```
<connectionStrings>
    <!--<add name="ApplicationServices" connectionString="data source=.\SQLEXPRESS;Integrated
Security=SSPI;AttachDBFilename=|DataDirectory|aspnetdb.mdf;User Instance=true"
providerName="System.Data.SqlClient"/>-->
  <add name="ApplicationServices" connectionString="data source=localhost;Integrated Security=SSPI;Initial
Catalog=MyProductionDB" />
</connectionStrings>
```

Configuring Database Permissions

If you use Integrated Security to connect to your database then you will need to add the correct Windows user account as a login to your database. The correct account depends on whether you are using the ASP.NET Development Server or Internet Information Services as your web server. The correct user account also depends on your operating system.

If you are using the ASP.NET Development Server (the default web server used by Visual Studio) then your application executes within the context of your Windows user account. In that case, you need to add your Windows user account as a database server login.

Alternatively, if you are using Internet Information Services then you need to add either the ASPNET account or the NT AUTHORITY/NETWORK SERVICE account as a database server login. If you are using Windows XP then add the ASPNET account as a login to your database. If you are using a more recent operating system, such as Windows Vista or Windows Server 2008, then add the NT AUTHORITY/NETWORK SERVICE account as the database login.

You can add a new user account to your database by using Microsoft SQL Server Management Studio (see Figure 9).

Figure 9 – Creating a new Microsoft SQL Server login

After you create the required login, you need to map the login to a database user with the right database roles. Double-click the login and select the User Mapping tab. Select one or more application services database roles. For example, in order to authenticate users, you need to enable the aspnet_Membership_BasicAccess database role. In order to create new users, you need to enable the aspnet_Membership_FullAccess database role (see Figure 10).

Figure 10 – Adding Application Services database roles

Summary

In this tutorial, you learned how to use Forms authentication when building an ASP.NET MVC application. First, you learned how to create new users and roles by taking advantage of the Web Site Administration Tool. Next, you learned how to use the [Authorize] attribute to prevent unauthorized users from invoking controller actions. Finally, you learned how to configure your MVC application to store user and role information in a production database.

Authenticating Users with Windows Authentication (C#)

4/10/2020 • 4 minutes to read • Edit Online

by Microsoft

Learn how to use Windows authentication in the context of an MVC application. You learn how to enable Windows authentication within your application's web configuration file and how to configure authentication with IIS. Finally, you learn how to use the [Authorize] attribute to restrict access to controller actions to particular Windows users or groups.

The goal of this tutorial is to explain how you can take advantage of the security features built into Internet Information Services to password protect the views in your MVC applications. You learn how to allow controller actions to be invoked only by particular Windows users or users who are members of particular Windows groups.

Using Windows authentication makes sense when you are building an internal company website (an intranet site) and you want your users to be able to use their standard Windows user names and passwords when accessing the website. If you are building an outwards facing website (an Internet website) consider using Forms authentication instead.

Enabling Windows Authentication

When you create a new ASP.NET MVC application, Windows authentication is not enabled by default. Forms authentication is the default authentication type enabled for MVC applications. You must enable Windows authentication by modifying your MVC application's web configuration (web.config) file. Find the <authentication> section and modify it to use Windows instead of Forms authentication like this:

```
<authentication mode="Windows">

</authentication>
```

When you enable Windows authentication, your web server becomes responsible for authenticating users. Typically, there are two different types of web servers that you use when creating and deploying an ASP.NET MVC application.

First, while developing an MVC application, you use the ASP.NET Development Web Server included with Visual Studio. By default, the ASP.NET Development Web Server executes all pages in the context of the current Windows account (whatever account you used to log into Windows).

The ASP.NET Development Web Server also supports NTLM authentication. You can enable NTLM authentication by right-clicking the name of your project in the Solution Explorer window and selecting Properties. Next, select the Web tab and check the NTLM checkbox (see Figure 1).

Figure 1 – Enabling NTLM authentication for the ASP.NET Development Web Server

For a production web application, on the hand, you use IIS as your web server. IIS supports several types of authentication including:

- Basic Authentication – Defined as part of the HTTP 1.0 protocol. Sends user names and passwords in clear text (Base64 encoded) across the Internet. - Digest Authentication – Sends a hash of a password, instead of the password itself, across the internet. - Integrated Windows (NTLM) Authentication – The best type of authentication to use in intranet environments using windows. - Certificate Authentication – Enables authentication using a client-side certificate. The certificate maps to a Windows user account.

> **NOTE**
>
> For a more detailed overview of these different types of authentication, see https://msdn.microsoft.com/library/aa292114(VS.71).aspx.

You can use Internet Information Services Manager to enable a particular type of authentication. Be aware that all types of authentication are not available in the case of every operating system. Furthermore, if you are using IIS 7.0 with Windows Vista, you will need to enable the different types of Windows authentication before they appear in the Internet Information Services Manager. Open **Control Panel, Programs, Programs and Features, Turn Windows features on or off**, and expand the Internet Information Services node (see Figure 2).

Figure 2 – Enabling Windows IIS features

Using Internet Information Services, you can enable or disable different types of authentication. For example,

Figure 3 illustrates disabling anonymous authentication and enabling Integrated Windows (NTLM) authentication when using IIS 7.0.

Figure 3 – Enabling Integrated Windows Authentication

Authorizing Windows Users and Groups

After you enable Windows authentication, you can use the [Authorize] attribute to control access to controllers or controller actions. This attribute can be applied to an entire MVC controller or a particular controller action.

For example, the Home controller in Listing 1 exposes three actions named Index(), CompanySecrets(), and StephenSecrets(). Anyone can invoke the Index() action. However, only members of the Windows local Managers group can invoke the CompanySecrets() action. Finally, only the Windows domain user named Stephen (in the Redmond domain) can invoke the StephenSecrets() action.

Listing 1 – Controllers\HomeController.cs

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using System.Web.Mvc;
using System.Web.Mvc.Ajax;

namespace MvcApplication1.Controllers
{
    [HandleError]
    public class HomeController : Controller
    {
        public ActionResult Index()
        {
            return View();
        }

        [Authorize(Roles = "Managers")]
        public ActionResult CompanySecrets()
        {
            return View();
        }

        [Authorize(Users="redmond\\swalther")]
        public ActionResult StephenSecrets()
        {
            return View();
        }

    }
}
```

NOTE

Because of Windows User Account Control (UAC), when working with Windows Vista or Windows Server 2008, the local Administrators group will behave differently than other groups. The [Authorize] attribute won't correctly recognize a member of the local Administrators group unless you modify your computer's UAC settings.

Exactly what happens when you attempt to invoke a controller action without being the right permissions depends on the type of authentication enabled. By default, when using the ASP.NET Development Server, you simply get a blank page. The page is served with a **401 Not Authorized** HTTP Response Status.

If, on the other hand, you are using IIS with Anonymous authentication disabled and Basic authentication enabled, then you keep getting a login dialog prompt each time you request the protected page (see Figure 4).

Figure 4 – Basic authentication login dialog

Summary

This tutorial explained how you can use Windows authentication in the context of an ASP.NET MVC application. You learned how to enable Windows authentication within your application's web configuration file and how to configure authentication with IIS. Finally, you learned how to use the [Authorize] attribute to restrict access to controller actions to particular Windows users or groups.

Preventing JavaScript Injection Attacks (C#)

2/20/2020 • 6 minutes to read • Edit Online

by Stephen Walther

Download PDF

Prevent JavaScript Injection Attacks and Cross-Site Scripting Attacks from happening to you. In this tutorial, Stephen Walther explains how you can easily defeat these types of attacks by HTML encoding your content.

The goal of this tutorial is to explain how you can prevent JavaScript injection attacks in your ASP.NET MVC applications. This tutorial discusses two approaches to defending your website against a JavaScript injection attack. You learn how to prevent JavaScript injection attacks by encoding the data that you display. You also learn how to prevent JavaScript injection attacks by encoding the data that you accept.

What is a JavaScript Injection Attack?

Whenever you accept user input and redisplay the user input, you open your website to JavaScript injection attacks. Let's examine a concrete application that is open to JavaScript injection attacks.

Imagine that you have created a customer feedback website (see Figure 1). Customers can visit the website and enter feedback on their experience using your products. When a customer submits their feedback, the feedback is redisplayed on the feedback page.

Figure 01: Customer Feedback Website (Click to view full-size image)

The customer feedback website uses the `controller` in Listing 1. This `controller` contains two actions named `Index()` and `Create()`.

Listing 1 – `HomeController.cs`

```
using System;
using System.Web.Mvc;
using CustomerFeedback.Models;

namespace CustomerFeedback.Controllers
{
     [HandleError]
     public class HomeController : Controller
     {
          private FeedbackDataContext db = new FeedbackDataContext();

          public ActionResult Index()
          {
               return View(db.Feedbacks);
          }

          public ActionResult Create(string message)

          {
               // Add feedback
               var newFeedback = new Feedback();
               newFeedback.Message = message;
               newFeedback.EntryDate = DateTime.Now;
               db.Feedbacks.InsertOnSubmit(newFeedback);
               db.SubmitChanges();

               // Redirect
               return RedirectToAction("Index");
          }
     }
}
```

The `Index()` method displays the `Index` view. This method passes all of the previous customer feedback to the `Index` view by retrieving the feedback from the database (using a LINQ to SQL query).

The `Create()` method creates a new Feedback item and adds it to the database. The message that the customer enters in the form is passed to the `Create()` method in the message parameter. A Feedback item is created and the message is assigned to the Feedback item's `Message` property. The Feedback item is submitted to the database with the `DataContext.SubmitChanges()` method call. Finally, the visitor is redirected back to the `Index` view where all of the feedback is displayed.

The `Index` view is contained in Listing 2.

Listing 2 – `Index.aspx`

```
<%@ Page Language="C#" MasterPageFile="~/Views/Shared/Site.Master" AutoEventWireup="true"
CodeBehind="Index.aspx.cs" Inherits="CustomerFeedback.Views.Home.Index"%>

<%@ Import Namespace="CustomerFeedback.Models" %>

<asp:Content ID="indexContent" ContentPlaceHolderID="MainContent" runat="server">
     <h1>Customer Feedback</h1>
     <p>
          Please use the following form to enter feedback about our product.
     </p>

     <form method="post" action="/Home/Create">

          <label for="message">Message:</label>
          <br />
          <textarea name="message" cols="50" rows="2"></textarea>
          <br /><br />
          <input type="submit" value="Submit Feedback" />
     </form>

     <% foreach (Feedback feedback in ViewData.Model)
     {%>
          <p>
          <%=feedback.EntryDate.ToShortTimeString()%>
          --
          <%=feedback.Message%>
          </p>
     <% }%>

</asp:Content>
```

The `Index` view has two sections. The top section contains the actual customer feedback form. The bottom section contains a For..Each loop that loops through all of the previous customer feedback items and displays the EntryDate and Message properties for each feedback item.

The customer feedback website is a simple website. Unfortunately, the website is open to JavaScript injection attacks.

Imagine that you enter the following text into the customer feedback form:

```
<script>alert("Boo!")</script>
```

This text represents a JavaScript script that displays an alert message box. After someone submits this script into the feedback form, the message *Boo!* will appear whenever anyone visits the customer feedback website in the future (see Figure 2).

Figure 02: JavaScript Injection (Click to view full-size image)

Now, your initial response to JavaScript injection attacks might be apathy. You might think that JavaScript injection attacks are simply a type of *defacement* attack. You might believe that no one can do anything truly evil by committing a JavaScript injection attack.

Unfortunately, a hacker can do some really, really evil things by injecting JavaScript into a website. You can use a JavaScript injection attack to perform a Cross-Site Scripting (XSS) attack. In a Cross-Site Scripting attack, you steal confidential user information and send the information to another website.

For example, a hacker can use a JavaScript injection attack to steal the values of browser cookies from other users. If sensitive information -- such as passwords, credit card numbers, or social security numbers – is stored in the browser cookies, then a hacker can use a JavaScript injection attack to steal this information. Or, if a user enters sensitive information in a form field contained in a page that has been compromised with a JavaScript attack, then the hacker can use the injected JavaScript to grab the form data and send it to another website.

Please be scared. Take JavaScript injection attacks seriously and protect your user's confidential information. In the next two sections, we discuss two techniques that you can use to defend your ASP.NET MVC applications from JavaScript injection attacks.

Approach #1: HTML Encode in the View

One easy method of preventing JavaScript injection attacks is to HTML encode any data entered by website users when you redisplay the data in a view. The updated `Index` view in Listing 3 follows this approach.

Listing 3 – `Index.aspx` (HTML Encoded)

```
<%@ Page Language="C#" MasterPageFile="~/Views/Shared/Site.Master" AutoEventWireup="true"
CodeBehind="Index.aspx.cs" Inherits="CustomerFeedback.Views.Home.Index"%>

<%@ Import Namespace="CustomerFeedback.Models" %>

<asp:Content ID="indexContent" ContentPlaceHolderID="MainContent" runat="server">
     <h1>Customer Feedback</h1>
     <p>
          Please use the following form to enter feedback about our product.
     </p>

     <form method="post" action="/Home/Create">
          <label for="message">Message:</label>
          <br />
          <textarea name="message" cols="50" rows="2"></textarea>
          <br /><br />
          <input type="submit" value="Submit Feedback" />

     </form>

     <% foreach (Feedback feedback in ViewData.Model)
     {%>
          <p>
          <%=feedback.EntryDate.ToShortTimeString()%>
          --
          <%=Html.Encode(feedback.Message)%>
          </p>
     <% }%>

</asp:Content>
```

Notice that the value of `feedback.Message` is HTML encoded before the value is displayed with the following code:

```
<%=Html.Encode(feedback.Message)%>
```

What does it mean to HTML encode a string? When you HTML encode a string, dangerous characters such as `<` and `>` are replaced by HTML entity references such as `<` and `>`. So when the string `<script>alert("Boo!")</script>` is HTML encoded, it gets converted to `<script>alert("Boo!")</script>`. The encoded string no longer executes as a JavaScript script when interpreted by a browser. Instead, you get the harmless page in Figure 3.

Figure 03: Defeated JavaScript Attack (Click to view full-size image)

Notice that in the `Index` view in Listing 3 only the value of `feedback.Message` is encoded. The value of `feedback.EntryDate` is not encoded. You only need to encode data entered by a user. Because the value of EntryDate was generated in the controller, you don't need to HTML encode this value.

Approach #2: HTML Encode in the Controller

Instead of HTML encoding data when you display the data in a view, you can HTML encode the data just before you submit the data to the database. This second approach is taken in the case of the `controller` in Listing 4.

Listing 4 – `HomeController.cs` (HTML Encoded)

```
using System;
using System.Web.Mvc;
using CustomerFeedback.Models;
namespace CustomerFeedback.Controllers
{
     [HandleError]
     public class HomeController : Controller
     {
          private FeedbackDataContext db = new FeedbackDataContext();

          public ActionResult Index()
          {
               return View(db.Feedbacks);
          }

          public ActionResult Create(string message)
          {
               // Add feedback
               var newFeedback = new Feedback();
               newFeedback.Message = Server.HtmlEncode(message);
               newFeedback.EntryDate = DateTime.Now;
               db.Feedbacks.InsertOnSubmit(newFeedback);

               db.SubmitChanges();

               // Redirect
               return RedirectToAction("Index");
          }
     }
}
```

Notice that the value of Message is HTML encoded before the value is submitted to the database within the `Create()` action. When the Message is redisplayed in the view, the Message is HTML encoded and any JavaScript injected in the Message is not executed.

Typically, you should favor the first approach discussed in this tutorial over this second approach. The problem with this second approach is that you end up with HTML encoded data in your database. In other words, your database data is dirtied with funny looking characters.

Why is this bad? If you ever need to display the database data in something other than a web page, then you will have problems. For example, you can no longer easily display the data in a Windows Forms application.

Summary

The purpose of this tutorial was to scare you about the prospect of a JavaScript injection attack. This tutorial discussed two approaches for defending your ASP.NET MVC applications against JavaScript injection attacks: you can either HTML encode user submitted data in the view or you can HTML encode user submitted data in the controller.

Authenticating Users with Forms Authentication (VB)

4/10/2020 • 7 minutes to read • Edit Online

by Microsoft

> Learn how to use the [Authorize] attribute to password protect particular pages in your MVC application. You learn how to use the Web Site Administration Tool to create and manage users and roles. You also learn how to configure where user account and role information is stored.

The goal of this tutorial is to explain how you can use Forms authentication to password protect the views in your ASP.NET MVC applications. You learn how to use the Web Site Administration Tool to create users and roles. You also learn how to prevent unauthorized users from invoking controller actions. Finally, you learn how to configure where user names and passwords are stored.

Using the Web Site Administration Tool

Before we do anything else, we should start by creating some users and roles. The easiest way to create new users and roles is to take advantage of the Visual Studio 2008 Web Site Administration Tool. You can launch this tool by selecting the menu option **Project, ASP.NET Configuration**. Alternatively, you can launch the Web Site Administration Tool by clicking the (somewhat scary) icon of the hammer hitting the world that appears at the top of the Solution Explorer window (see Figure 1).

Figure 1 – Launching the Web Site Administration Tool

Within the Web Site Administration Tool, you create new users and roles by selecting the Security tab. Click the **Create user** link to create a new user named Stephen (see Figure 2). Provide the Stephen user with any password that you want (for example, *secret*).

Figure 2 – Creating a new user

You create new roles by first enabling roles and defining one or more roles. Enable roles by clicking the **Enable roles** link. Next, create a role named *Administrators* by clicking the **Create or Manage roles** link (see Figure 3).

Figure 3 – Creating a new role

Finally, create a new user named Sally and associate Sally with the Administrators role by clicking the Create User link and selecting Administrators when creating Sally (see Figure 4).

Figure 4 – Adding a user to a role

When all is said and done, you should have two new users named Stephen and Sally. You should also have a new

role named Administrators. Sally is a member of the Administrators role and Stephen is not.

Requiring Authorization

You can require a user to be authenticated before the user invokes a controller action by adding the [Authorize] attribute to the action. You can apply the [Authorize] attribute to an individual controller action or you can apply this attribute to an entire controller class.

For example, the controller in Listing 1 exposes an action named CompanySecrets(). Because this action is decorated with the [Authorize] attribute, this action cannot be invoked unless a user is authenticated.

Listing 1 – Controllers\HomeController.vb

```
<HandleError()> _
Public Class HomeController
    Inherits System.Web.Mvc.Controller

    Function Index()
        Return View()
    End Function

    <Authorize()> _
    Function CompanySecrets()
        Return View()
    End Function

End Class
```

If you invoke the CompanySecrets() action by entering the URL /Home/CompanySecrets in the address bar of your browser, and you are not an authenticated user, then you will be redirected to the Login view automatically (see Figure 5).

Figure 5 – The Login view

You can use the Login view to enter your user name and password. If you are not a registered user then you can click the **register** link to navigate to the Register view (see Figure 6). You can use the Register view to create a new user account.

Figure 6 – The Register view

After you successfully log in, you can see the CompanySecrets view (see Figure 7). By default, you will continue to be logged in until you close your browser window.

Figure 7 – The CompanySecrets view

Authorizing by User Name or User Role

You can use the [Authorize] attribute to restrict access to a controller action to a particular set of users or a particular set of user roles. For example, the modified Home controller in Listing 2 contains two new actions named StephenSecrets() and AdministratorSecrets().

Listing 2 – Controllers\HomeController.vb

```
<HandleError()> _
Public Class HomeController
    Inherits System.Web.Mvc.Controller

    Function Index()
        Return View()
    End Function

    <Authorize()> _
    Function CompanySecrets()
        Return View()
    End Function

    <Authorize(Users:="Stephen")> _
    Function StephenSecrets()
        Return View()
    End Function

    <Authorize(Roles:="Administrators")> _
    Function AdministratorSecrets()
        Return View()
    End Function

End Class
```

Only a user with the user name Stephen can invoke the StephenSecrets() action. All other users get redirected to the Login view. The Users property accepts a comma separated list of user account names.

Only users in the Administrators role can invoke the AdministratorSecrets() action. For example, because Sally is a member of the Administrators group, she can invoke the AdministratorSecrets() action. All other users get redirected to the Login view. The Roles property accepts a comma separated list of role names.

Configuring Authentication

At this point, you might be wondering where the user account and role information is being stored. By default, the information is stored in a (RANU) SQL Express database named ASPNETDB.mdf located in your MVC application's App_Data folder. This database is generated by the ASP.NET framework automatically when you start using membership.

In order to see the ASPNETDB.mdf database in the Solution Explorer window, you first need to select the menu option Project, Show All Files.

Using the default SQL Express database is fine when developing an application. Most likely, however, you won't want to use the default ASPNETDB.mdf database for a production application. In that case, you can change where user account information is stored by completing the following two steps:

1. Add the Application Services database objects to your production database - Change your application connection string to point to your production database

The first step is to add all of the necessary database objects (tables and stored procedures) to your production database. The easiest way to add these objects to a new database is to take advantage of the ASP.NET SQL Server Setup Wizard (see Figure 8). You can launch this tool by opening the Visual Studio 2008 Command Prompt from the Microsoft Visual Studio 2008 program group and executing the following command from the command prompt:

aspnet_regsql

Figure 8 – The ASP.NET SQL Server Setup Wizard

The ASP.NET SQL Server Setup Wizard enables you to select a SQL Server database on your network and install all of the database objects required by the ASP.NET application services. The database server is not required to be located on your local machine.

> **NOTE**
>
> If you don't want to use the ASP.NET SQL Server Setup Wizard, then you can find SQL scripts for adding the application services database objects in the following folder:
>
> C:\Windows\Microsoft.NET\Framework\v2.0.50727

After you create the necessary database objects, you need to modify the database connection used by your MVC application. Modify the ApplicationServices connection string in your web configuration (web.config) file so that it points to the production database. For example, the modified connection in Listing 3 points to a database named MyProductionDB (the original ApplicationServices connection string has been commented out).

Listing 3 – Web.config

```
<connectionStrings>

<!--<add name="ApplicationServices" connectionString="data source=.\SQLEXPRESS;Integrated
Security=SSPI;AttachDBFilename=|DataDirectory|aspnetdb.mdf;User Instance=true"
providerName="System.Data.SqlClient"/>-->

<add name="ApplicationServices" connectionString="data source=localhost;Integrated Security=SSPI;Initial
Catalog=MyProductionDB" />

</connectionStrings>
```

Configuring Database Permissions

If you use Integrated Security to connect to your database then you will need to add the correct Windows user account as a login to your database. The correct account depends on whether you are using the ASP.NET Development Server or Internet Information Services as your web server. The correct user account also depends on your operating system.

If you are using the ASP.NET Development Server (the default web server used by Visual Studio) then your

application executes within the context of your Windows user account. In that case, you need to add your Windows user account as a database server login.

Alternatively, if you are using Internet Information Services then you need to add either the ASPNET account or the NT AUTHORITY/NETWORK SERVICE account as a database server login. If you are using Windows XP then add the ASPNET account as a login to your database. If you are using a more recent operating system, such as Windows Vista or Windows Server 2008, then add the NT AUTHORITY/NETWORK SERVICE account as the database login.

You can add a new user account to your database by using Microsoft SQL Server Management Studio (see Figure 9).

Figure 9 – Creating a new Microsoft SQL Server login

After you create the required login, you need to map the login to a database user with the right database roles. Double-click the login and select the User Mapping tab. Select one or more application services database roles. For example, in order to authenticate users, you need to enable the aspnet_Membership_BasicAccess database role. In order to create new users, you need to enable the aspnet_Membership_FullAccess database role (see Figure 10).

Figure 10 – Adding Application Services database roles

Summary

In this tutorial, you learned how to use Forms authentication when building an ASP.NET MVC application. First, you learned how to create new users and roles by taking advantage of the Web Site Administration Tool. Next, you learned how to use the [Authorize] attribute to prevent unauthorized users from invoking controller actions. Finally, you learned how to configure your MVC application to store user and role information in a production database.

Authenticating Users with Windows Authentication (VB)

4/10/2020 • 4 minutes to read • Edit Online

by Microsoft

Learn how to use Windows authentication in the context of an MVC application. You learn how to enable Windows authentication within your application's web configuration file and how to configure authentication with IIS. Finally, you learn how to use the [Authorize] attribute to restrict access to controller actions to particular Windows users or groups.

The goal of this tutorial is to explain how you can take advantage of the security features built into Internet Information Services to password protect the views in your MVC applications. You learn how to allow controller actions to be invoked only by particular Windows users or users who are members of particular Windows groups.

Using Windows authentication makes sense when you are building an internal company website (an intranet site) and you want your users to be able to use their standard Windows user names and passwords when accessing the website. If you are building an outwards facing website (an Internet website) consider using Forms authentication instead.

Enabling Windows Authentication

When you create a new ASP.NET MVC application, Windows authentication is not enabled by default. Forms authentication is the default authentication type enabled for MVC applications. You must enable Windows authentication by modifying your MVC application's web configuration (web.config) file. Find the <authentication> section and modify it to use Windows instead of Forms authentication like this:

```
<authentication mode="Windows">

</authentication>
```

When you enable Windows authentication, your web server becomes responsible for authenticating users. Typically, there are two different types of web servers that you use when creating and deploying an ASP.NET MVC application.

First, while developing an MVC application, you use the ASP.NET Development Web Server included with Visual Studio. By default, the ASP.NET Development Web Server executes all pages in the context of the current Windows account (whatever account you used to log into Windows).

The ASP.NET Development Web Server also supports NTLM authentication. You can enable NTLM authentication by right-clicking the name of your project in the Solution Explorer window and selecting Properties. Next, select the Web tab and check the NTLM checkbox (see Figure 1).

Figure 1 – Enabling NTLM authentication for the ASP.NET Development Web Server

For a production web application, on the hand, you use IIS as your web server. IIS supports several types of authentication including:

- Basic Authentication – Defined as part of the HTTP 1.0 protocol. Sends user names and passwords in clear text (Base64 encoded) across the Internet. - Digest Authentication – Sends a hash of a password, instead of the password itself, across the internet. - Integrated Windows (NTLM) Authentication – The best type of authentication to use in intranet environments using windows. - Certificate Authentication – Enables authentication using a client-side certificate. The certificate maps to a Windows user account.

> **NOTE**
>
> For a more detailed overview of these different types of authentication, see https://msdn.microsoft.com/library/aa292114(VS.71).aspx.

You can use Internet Information Services Manager to enable a particular type of authentication. Be aware that all types of authentication are not available in the case of every operating system. Furthermore, if you are using IIS 7.0 with Windows Vista, you will need to enable the different types of Windows authentication before they appear in the Internet Information Services Manager. Open **Control Panel, Programs, Programs and Features, Turn Windows features on or off**, and expand the Internet Information Services node (see Figure 2).

Figure 2 – Enabling Windows IIS features

Using Internet Information Services, you can enable or disable different types of authentication. For example,

Figure 3 illustrates disabling anonymous authentication and enabling Integrated Windows (NTLM) authentication when using IIS 7.0.

Figure 3 – Enabling Integrated Windows Authentication

Authorizing Windows Users and Groups

After you enable Windows authentication, you can use the <Authorize> attribute to control access to controllers or controller actions. This attribute can be applied to an entire MVC controller or a particular controller action.

For example, the Home controller in Listing 1 exposes three actions named Index(), CompanySecrets(), and StephenSecrets(). Anyone can invoke the Index() action. However, only members of the Windows local Managers group can invoke the CompanySecrets() action. Finally, only the Windows domain user named Stephen (in the Redmond domain) can invoke the StephenSecrets() action.

Listing 1 – Controllers\HomeController.vb

```
<HandleError()> _
Public Class HomeController
    Inherits System.Web.Mvc.Controller

    Function Index()
        Return View()
    End Function

    <Authorize(Roles:="Managers")> _
    Function CompanySecrets()
        Return View()
    End Function

    <Authorize(Users:="redmond\swalther")> _
    Function StephenSecrets()
        Return View()
    End Function

End Class
```

> **NOTE**
>
> Because of Windows User Account Control (UAC), when working with Windows Vista or Windows Server 2008, the local Administrators group will behave differently than other groups. The <Authorize> attribute won't correctly recognize a member of the local Administrators group unless you modify your computer's UAC settings.

Exactly what happens when you attempt to invoke a controller action without being the right permissions depends on the type of authentication enabled. By default, when using the ASP.NET Development Server, you simply get a blank page. The page is served with a **401 Not Authorized** HTTP Response Status.

If, on the other hand, you are using IIS with Anonymous authentication disabled and Basic authentication enabled, then you keep getting a login dialog prompt each time you request the protected page (see Figure 4).

Figure 4 – Basic authentication login dialog

Summary

This tutorial explained how you can use Windows authentication in the context of an ASP.NET MVC application. You learned how to enable Windows authentication within your application's web configuration file and how to configure authentication with IIS. Finally, you learned how to use the <Authorize> attribute to restrict access to controller actions to particular Windows users or groups.

Preventing JavaScript Injection Attacks (VB)

2/20/2020 • 6 minutes to read • Edit Online

by Stephen Walther

Download PDF

Prevent JavaScript Injection Attacks and Cross-Site Scripting Attacks from happening to you. In this tutorial, Stephen Walther explains how you can easily defeat these types of attacks by HTML encoding your content.

The goal of this tutorial is to explain how you can prevent JavaScript injection attacks in your ASP.NET MVC applications. This tutorial discusses two approaches to defending your website against a JavaScript injection attack. You learn how to prevent JavaScript injection attacks by encoding the data that you display. You also learn how to prevent JavaScript injection attacks by encoding the data that you accept.

What is a JavaScript Injection Attack?

Whenever you accept user input and redisplay the user input, you open your website to JavaScript injection attacks. Let's examine a concrete application that is open to JavaScript injection attacks.

Imagine that you have created a customer feedback website (see Figure 1). Customers can visit the website and enter feedback on their experience using your products. When a customer submits their feedback, the feedback is redisplayed on the feedback page.

Figure 01: Customer Feedback Website (Click to view full-size image)

The customer feedback website uses the `controller` in Listing 1. This `controller` contains two actions named `Index()` and `Create()`.

Listing 1 – `HomeController.vb`

```
Public Class HomeController
     Inherits System.Web.Mvc.Controller

     Private db As New FeedbackDataContext()

     Function Index()
          Return View(db.Feedbacks)
     End Function

     Function Create(ByVal message As String)
          ' Add feedback
          Dim newFeedback As New Feedback()
          newFeedback.Message = Server.HtmlEncode(message)

          newFeedback.EntryDate = DateTime.Now
          db.Feedbacks.InsertOnSubmit(newFeedback)
          db.SubmitChanges()

          ' Redirect
          Return RedirectToAction("Index")
     End Function

End Class
```

The `Index()` method displays the `Index` view. This method passes all of the previous customer feedback to the `Index` view by retrieving the feedback from the database (using a LINQ to SQL query).

The `Create()` method creates a new Feedback item and adds it to the database. The message that the customer enters in the form is passed to the `Create()` method in the message parameter. A Feedback item is created and the message is assigned to the Feedback item's `Message` property. The Feedback item is submitted to the database with the `DataContext.SubmitChanges()` method call. Finally, the visitor is redirected back to the `Index` view where all of the feedback is displayed.

The `Index` view is contained in Listing 2.

Listing 2 – `Index.aspx`

```
<%@ Page Language="VB" MasterPageFile="~/Views/Shared/Site.Master" AutoEventWireup="false"
CodeBehind="Index.aspx.vb" Inherits="CustomerFeedback.Index"%>

<asp:Content ID="indexContent" ContentPlaceHolderID="MainContent" runat="server">
     <h1>Customer Feedback</h1>
     <p>
          Please use the following form to enter feedback about our product.
     </p>
     <form method="post" action="/Home/Create">
          <label for="message">Message:</label>

          <br />
          <textarea name="message" cols="50" rows="2"></textarea>
          <br /><br />
          <input type="submit" value="Submit Feedback" />
     </form>

     <% For Each feedback As CustomerFeedback.Feedback In ViewData.Model%>
          <p>

          <%=feedback.EntryDate.ToShortTimeString()%>
          --
          <%=feedback.Message%>
          </p>
     <% Next %>

</asp:Content>
```

The `Index` view has two sections. The top section contains the actual customer feedback form. The bottom section contains a For..Each loop that loops through all of the previous customer feedback items and displays the EntryDate and Message properties for each feedback item.

The customer feedback website is a simple website. Unfortunately, the website is open to JavaScript injection attacks.

Imagine that you enter the following text into the customer feedback form:

```
<script>alert("Boo!")</script>
```

This text represents a JavaScript script that displays an alert message box. After someone submits this script into the feedback form, the message *Boo!* will appear whenever anyone visits the customer feedback website in the future (see Figure 2).

Figure 02: JavaScript Injection (Click to view full-size image)

Now, your initial response to JavaScript injection attacks might be apathy. You might think that JavaScript injection attacks are simply a type of *defacement* attack. You might believe that no one can do anything truly evil by committing a JavaScript injection attack.

Unfortunately, a hacker can do some really, really evil things by injecting JavaScript into a website. You can use a JavaScript injection attack to perform a Cross-Site Scripting (XSS) attack. In a Cross-Site Scripting attack, you steal confidential user information and send the information to another website.

For example, a hacker can use a JavaScript injection attack to steal the values of browser cookies from other users. If sensitive information -- such as passwords, credit card numbers, or social security numbers – is stored in the browser cookies, then a hacker can use a JavaScript injection attack to steal this information. Or, if a user enters sensitive information in a form field contained in a page that has been compromised with a JavaScript attack, then the hacker can use the injected JavaScript to grab the form data and send it to another website.

Please be scared. Take JavaScript injection attacks seriously and protect your user's confidential information. In the next two sections, we discuss two techniques that you can use to defend your ASP.NET MVC applications from JavaScript injection attacks.

Approach #1: HTML Encode in the View

One easy method of preventing JavaScript injection attacks is to HTML encode any data entered by website users when you redisplay the data in a view. The updated `Index` view in Listing 3 follows this approach.

Listing 3 – `Index.aspx` (HTML Encoded)

```
<%@ Page Language="VB" MasterPageFile="~/Views/Shared/Site.Master" AutoEventWireup="false"
CodeBehind="Index.aspx.vb" Inherits="CustomerFeedback.Index"%>

<asp:Content ID="indexContent" ContentPlaceHolderID="MainContent" runat="server">
     <h1>Customer Feedback</h1>

     <p>
          Please use the following form to enter feedback about our product.
     </p>

     <form method="post" action="/Home/Create">
          <label for="message">Message:</label>
          <br />
          <textarea name="message" cols="50" rows="2"></textarea>

          <br /><br />
          <input type="submit" value="Submit Feedback" />
     </form>

     <% For Each feedback As CustomerFeedback.Feedback In ViewData.Model%>
          <p>
          <%=feedback.EntryDate.ToShortTimeString()%>
          --
          <%=Html.Encode(feedback.Message)%>

          </p>
     <% Next %>

</asp:Content>
```

Notice that the value of `feedback.Message` is HTML encoded before the value is displayed with the following code:

```
<%=Html.Encode(feedback.Message)%>
```

What does it mean to HTML encode a string? When you HTML encode a string, dangerous characters such as `<` and `>` are replaced by HTML entity references such as `<` and `>`. So when the string `<script>alert("Boo!")</script>` is HTML encoded, it gets converted to `<script>alert("Boo!")</script>`. The encoded string no longer executes as a JavaScript script when interpreted by a browser. Instead, you get the harmless page in Figure 3.

Figure 03: Defeated JavaScript Attack (Click to view full-size image)

Notice that in the `Index` view in Listing 3 only the value of `feedback.Message` is encoded. The value of

`feedback.EntryDate` is not encoded. You only need to encode data entered by a user. Because the value of EntryDate was generated in the controller, you don't need to HTML encode this value.

Approach #2: HTML Encode in the Controller

Instead of HTML encoding data when you display the data in a view, you can HTML encode the data just before you submit the data to the database. This second approach is taken in the case of the `controller` in Listing 4.

Listing 4 – `HomeController.cs` (HTML Encoded)

```
Public Class HomeController
     Inherits System.Web.Mvc.Controller

     Private db As New FeedbackDataContext()

     Function Index()
          Return View(db.Feedbacks)
     End Function

     Function Create(ByVal message As String)
          ' Add feedback
          Dim newFeedback As New Feedback()
          newFeedback.Message = Server.HtmlEncode(message)
          newFeedback.EntryDate = DateTime.Now
          db.Feedbacks.InsertOnSubmit(newFeedback)
          db.SubmitChanges()

          ' Redirect
          Return RedirectToAction("Index")
     End Function

End Class
```

Notice that the value of Message is HTML encoded before the value is submitted to the database within the `Create()` action. When the Message is redisplayed in the view, the Message is HTML encoded and any JavaScript injected in the Message is not executed.

Typically, you should favor the first approach discussed in this tutorial over this second approach. The problem with this second approach is that you end up with HTML encoded data in your database. In other words, your database data is dirtied with funny looking characters.

Why is this bad? If you ever need to display the database data in something other than a web page, then you will have problems. For example, you can no longer easily display the data in a Windows Forms application.

Summary

The purpose of this tutorial was to scare you about the prospect of a JavaScript injection attack. This tutorial discussed two approaches for defending your ASP.NET MVC applications against JavaScript injection attacks: you can either HTML encode user submitted data in the view or you can HTML encode user submitted data in the controller.

Creating Unit Tests for ASP.NET MVC Applications (C#)

2/20/2020 • 6 minutes to read • Edit Online

by Stephen Walther

Download PDF

Learn how to create unit tests for controller actions. In this tutorial, Stephen Walther demonstrates how to test whether a controller action returns a particular view, returns a particular set of data, or returns a different type of action result.

The goal of this tutorial is to demonstrate how you can write unit tests for the controllers in your ASP.NET MVC applications. We discuss how to build three different types of unit tests. You learn how to test the view returned by a controller action, how to test the View Data returned by a controller action, and how to test whether or not one controller action redirects you to a second controller action.

Creating the Controller under Test

Let's start by creating the controller that we intend to test. The controller, named the `ProductController`, is contained in Listing 1.

Listing 1 – `ProductController.cs`

```
using System;
using System.Web.Mvc;

namespace Store.Controllers
{
     public class ProductController : Controller
     {
          public ActionResult Index()
          {
               // Add action logic here
               throw new NotImplementedException();
          }

          public ActionResult Details(int Id)
          {

               return View("Details");
          }
     }
}
```

The `ProductController` contains two action methods named `Index()` and `Details()`. Both action methods return a view. Notice that the `Details()` action accepts a parameter named Id.

Testing the View returned by a Controller

Imagine that we want to test whether or not the `ProductController` returns the right view. We want to make sure that when the `ProductController.Details()` action is invoked, the Details view is returned. The test class in Listing 2 contains a unit test for testing the view returned by the `ProductController.Details()` action.

Listing 2 – `ProductControllerTest.cs`

```
using System.Web.Mvc;
using Microsoft.VisualStudio.TestTools.UnitTesting;
using Store.Controllers;

namespace StoreTests.Controllers
{
     [TestClass]
     public class ProductControllerTest
     {
          [TestMethod]
          public void TestDetailsView()
          {
               var controller = new ProductController();
               var result = controller.Details(2) as ViewResult;
               Assert.AreEqual("Details", result.ViewName);

          }
     }
}
```

The class in Listing 2 includes a test method named `TestDetailsView()`. This method contains three lines of code. The first line of code creates a new instance of the `ProductController` class. The second line of code invokes the controller's `Details()` action method. Finally, the last line of code checks whether or not the view returned by the `Details()` action is the Details view.

The `ViewResult.ViewName` property represents the name of the view returned by a controller. One big warning about testing this property. There are two ways that a controller can return a view. A controller can explicitly return a view like this:

```
public ActionResult Details(int Id)
{
     return View("Details");
}
```

Alternatively, the name of the view can be inferred from the name of the controller action like this:

```
public ActionResult Details(int Id)
{
     return View();
}
```

This controller action also returns a view named `Details`. However, the name of the view is inferred from the action name. If you want to test the view name, then you must explicitly return the view name from the controller action.

You can run the unit test in Listing 2 by either entering the keyboard combination **Ctrl-R, A** or by clicking the **Run All Tests in Solution** button (see Figure 1). If the test passes, you'll see the Test Results window in Figure 2.

Figure 01: Run All Tests in Solution (Click to view full-size image)

Figure 02: Success! (Click to view full-size image)

Testing the View Data returned by a Controller

An MVC controller passes data to a view by using something called `View Data`. For example, imagine that you want to display the details for a particular product when you invoke the `ProductController Details()` action. In that case, you can create an instance of a `Product` class (defined in your model) and pass the instance to the `Details` view by taking advantage of `View Data`.

The modified `ProductController` in Listing 3 includes an updated `Details()` action that returns a Product.

Listing 3 – `ProductController.cs`

```
using System;
using System.Web.Mvc;

namespace Store.Controllers
{
     public class ProductController : Controller
     {
          public ActionResult Index()
          {
               // Add action logic here
               throw new NotImplementedException();
          }

          public ActionResult Details(int Id)
          {
               var product = new Product(Id, "Laptop");
               return View("Details", product);
          }
     }
}
```

First, the `Details()` action creates a new instance of the `Product` class that represents a laptop computer. Next, the instance of the `Product` class is passed as the second parameter to the `View()` method.

You can write unit tests to test whether the expected data is contained in view data. The unit test in Listing 4 tests whether or not a Product representing a laptop computer is returned when you call the `ProductController Details()` action method.

Listing 4 – `ProductControllerTest.cs`

```
using System.Web.Mvc;
using Microsoft.VisualStudio.TestTools.UnitTesting;
using Store.Controllers;

namespace StoreTests.Controllers
{
     [TestClass]
     public class ProductControllerTest
     {

          [TestMethod]
          public void TestDetailsViewData()
          {
               var controller = new ProductController();
               var result = controller.Details(2) as ViewResult;
               var product = (Product) result.ViewData.Model;
               Assert.AreEqual("Laptop", product.Name);
          }
     }
}
```

In Listing 4, the `TestDetailsView()` method tests the View Data returned by invoking the `Details()` method. The `ViewData` is exposed as a property on the `ViewResult` returned by invoking the `Details()` method. The `ViewData.Model` property contains the product passed to the view. The test simply verifies that the product contained in the View Data has the name Laptop.

Testing the Action Result returned by a Controller

A more complex controller action might return different types of action results depending on the values of the parameters passed to the controller action. A controller action can return a variety of types of action results including a `ViewResult`, `RedirectToRouteResult`, or `JsonResult`.

For example, the modified `Details()` action in Listing 5 returns the `Details` view when you pass a valid product Id to the action. If you pass an invalid product Id -- an Id with a value less than 1 -- then you are redirected to the `Index()` action.

Listing 5 – `ProductController.cs`

```
using System;
using System.Web.Mvc;
namespace Store.Controllers
{
     public class ProductController : Controller
     {
          public ActionResult Index()
          {
               // Add action logic here
               throw new NotImplementedException();
          }
          public ActionResult Details(int Id)
          {
               if (Id < 1)
                    return RedirectToAction("Index");
               var product = new Product(Id, "Laptop");
               return View("Details", product);

          }
     }
}
```

You can test the behavior of the `Details()` action with the unit test in Listing 6. The unit test in Listing 6 verifies

that you are redirected to the `Index` view when an Id with the value -1 is passed to the `Details()` method.

Listing 6 – `ProductControllerTest.cs`

```
using System.Web.Mvc;
using Microsoft.VisualStudio.TestTools.UnitTesting;
using Store.Controllers;
namespace StoreTests.Controllers
{
     [TestClass]
     public class ProductControllerTest
     {
          [TestMethod]
          public void TestDetailsRedirect()
          {
               var controller = new ProductController();
               var result = (RedirectToRouteResult) controller.Details(-1);
               Assert.AreEqual("Index", result.Values["action"]);

          }
     }
}
```

When you call the `RedirectToAction()` method in a controller action, the controller action returns a `RedirectToRouteResult`. The test checks whether the `RedirectToRouteResult` will redirect the user to a controller action named `Index`.

Summary

In this tutorial, you learned how to build unit tests for MVC controller actions. First, you learned how to verify whether the right view is returned by a controller action. You learned how to use the `ViewResult.ViewName` property to verify the name of a view.

Next, we examined how you can test the contents of `View Data`. You learned how to check whether the right product was returned in `View Data` after calling a controller action.

Finally, we discussed how you can test whether different types of action results are returned from a controller action. You learned how to test whether a controller returns a `ViewResult` or a `RedirectToRouteResult`.

Creating Unit Tests for ASP.NET MVC Applications (VB)

2/20/2020 • 6 minutes to read • Edit Online

by Stephen Walther

Download PDF

Learn how to create unit tests for controller actions. In this tutorial, Stephen Walther demonstrates how to test whether a controller action returns a particular view, returns a particular set of data, or returns a different type of action result.

The goal of this tutorial is to demonstrate how you can write unit tests for the controllers in your ASP.NET MVC applications. We discuss how to build three different types of unit tests. You learn how to test the view returned by a controller action, how to test the View Data returned by a controller action, and how to test whether or not one controller action redirects you to a second controller action.

Creating the Controller under Test

Let's start by creating the controller that we intend to test. The controller, named the `ProductController`, is contained in Listing 1.

Listing 1 – `ProductController.vb`

```
Public Class ProductController
     Inherits System.Web.Mvc.Controller

     Function Index()
          ' Add action logic here
          Throw New NotImplementedException()
     End Function

     Function Details(ByVal Id As Integer)
          Return View("Details")
     End Function
End Class
```

The `ProductController` contains two action methods named `Index()` and `Details()`. Both action methods return a view. Notice that the `Details()` action accepts a parameter named Id.

Testing the View returned by a Controller

Imagine that we want to test whether or not the `ProductController` returns the right view. We want to make sure that when the `ProductController.Details()` action is invoked, the Details view is returned. The test class in Listing 2 contains a unit test for testing the view returned by the `ProductController.Details()` action.

Listing 2 – `ProductControllerTest.vb`

```
Imports Microsoft.VisualStudio.TestTools.UnitTesting
Imports System.Web.Mvc
Imports Store

<TestClass()> Public Class ProductControllerTest
     <TestMethod()> Public Sub TestDetailsView()
          Dim controller As New ProductController()
          Dim result As ViewResult = controller.Details(2)
          Assert.AreEqual("Details", result.ViewName)

     End Sub
End Class
```

The class in Listing 2 includes a test method named `TestDetailsView()`. This method contains three lines of code. The first line of code creates a new instance of the `ProductController` class. The second line of code invokes the controller's `Details()` action method. Finally, the last line of code checks whether or not the view returned by the `Details()` action is the Details view.

The `ViewResult.ViewName` property represents the name of the view returned by a controller. One big warning about testing this property. There are two ways that a controller can return a view. A controller can explicitly return a view like this:

```
Function Details(ByVal Id As Integer)
     Return View("Details")
End Function
```

Alternatively, the name of the view can be inferred from the name of the controller action like this:

```
Function Details(ByVal Id As Integer)
     Return View()
End Function
```

This controller action also returns a view named `Details`. However, the name of the view is inferred from the action name. If you want to test the view name, then you must explicitly return the view name from the controller action.

You can run the unit test in Listing 2 by either entering the keyboard combination **Ctrl-R, A** or by clicking the **Run All Tests in Solution** button (see Figure 1). If the test passes, you'll see the Test Results window in Figure 2.

Figure 01: Run All Tests in Solution (Click to view full-size image)

Figure 02: Success! (Click to view full-size image)

Testing the View Data returned by a Controller

An MVC controller passes data to a view by using something called `View Data`. For example, imagine that you want to display the details for a particular product when you invoke the `ProductController Details()` action. In that case, you can create an instance of a `Product` class (defined in your model) and pass the instance to the `Details` view by taking advantage of `View Data`.

The modified `ProductController` in Listing 3 includes an updated `Details()` action that returns a Product.

Listing 3 – `ProductController.vb`

```
Public Class ProductController
     Inherits System.Web.Mvc.Controller

     Function Index()
          ' Add action logic here
          Throw New NotImplementedException()
     End Function

     Function Details(ByVal Id As Integer)
          Dim product As New Product(Id, "Laptop")
          Return View("Details", product)
     End Function
End Class
```

First, the `Details()` action creates a new instance of the `Product` class that represents a laptop computer. Next, the instance of the `Product` class is passed as the second parameter to the `View()` method.

You can write unit tests to test whether the expected data is contained in view data. The unit test in Listing 4 tests whether or not a Product representing a laptop computer is returned when you call the `ProductController Details()` action method.

Listing 4 – `ProductControllerTest.vb`

```
Imports Microsoft.VisualStudio.TestTools.UnitTesting
Imports System.Web.Mvc
Imports Store

<TestClass()> Public Class ProductControllerTest

     <TestMethod()> Public Sub TestDetailsViewData()
          Dim controller As New ProductController()
          Dim result As ViewResult = controller.Details(2)
          Dim product As Product = result.ViewData.Model
          Assert.AreEqual("Laptop", product.Name)
     End Sub
End Class
```

In Listing 4, the `TestDetailsView()` method tests the View Data returned by invoking the `Details()` method. The `ViewData` is exposed as a property on the `ViewResult` returned by invoking the `Details()` method. The `ViewData.Model` property contains the product passed to the view. The test simply verifies that the product contained in the View Data has the name Laptop.

Testing the Action Result returned by a Controller

A more complex controller action might return different types of action results depending on the values of the parameters passed to the controller action. A controller action can return a variety of types of action results

including a `ViewResult`, `RedirectToRouteResult`, or `JsonResult`.

For example, the modified `Details()` action in Listing 5 returns the `Details` view when you pass a valid product Id to the action. If you pass an invalid product Id -- an Id with a value less than 1 -- then you are redirected to the `Index()` action.

Listing 5 – `ProductController.vb`

```
Public Class ProductController
     Inherits System.Web.Mvc.Controller

     Function Index()
          ' Add action logic here
          Throw New NotImplementedException()
     End Function

     Function Details(ByVal Id As Integer)
          If Id < 1 Then
               Return RedirectToAction("Index")
          End If
          Dim product As New Product(Id, "Laptop")
          Return View("Details", product)
     End Function
End Class
```

You can test the behavior of the `Details()` action with the unit test in Listing 6. The unit test in Listing 6 verifies that you are redirected to the `Index` view when an Id with the value -1 is passed to the `Details()` method.

Listing 6 – `ProductControllerTest.vb`

```
Imports Microsoft.VisualStudio.TestTools.UnitTesting
Imports System.Web.Mvc
Imports Store

<TestClass()> Public Class ProductControllerTest

     <TestMethod()> Public Sub TestDetailsRedirect()
          Dim controller As New ProductController()
          Dim result As RedirectToRouteResult = controller.Details(-1)
          Assert.AreEqual("Index", result.Values("action"))
     End Sub
End Class
```

When you call the `RedirectToAction()` method in a controller action, the controller action returns a `RedirectToRouteResult`. The test checks whether the `RedirectToRouteResult` will redirect the user to a controller action named `Index`.

Summary

In this tutorial, you learned how to build unit tests for MVC controller actions. First, you learned how to verify whether the right view is returned by a controller action. You learned how to use the `ViewResult.ViewName` property to verify the name of a view.

Next, we examined how you can test the contents of `View Data`. You learned how to check whether the right product was returned in `View Data` after calling a controller action.

Finally, we discussed how you can test whether different types of action results are returned from a controller action. You learned how to test whether a controller returns a `ViewResult` or a `RedirectToRouteResult`.

> In the first iteration, we create the Contact Manager in the simplest way possible. We add support for basic database operations: Create, Read, Update, and Delete (CRUD).

Building a Contact Management ASP.NET MVC Application (VB)

In this series of tutorials, we build an entire Contact Management application from start to finish. The Contact Manager application enables you to store contact information - names, phone numbers and email addresses - for a list of people.

We build the application over multiple iterations. With each iteration, we gradually improve the application. The goal of this multiple iteration approach is to enable you to understand the reason for each change.

- Iteration #1 - Create the application. In the first iteration, we create the Contact Manager in the simplest way possible. We add support for basic database operations: Create, Read, Update, and Delete (CRUD).
- Iteration #2 - Make the application look nice. In this iteration, we improve the appearance of the application by modifying the default ASP.NET MVC view master page and cascading style sheet.
- Iteration #3 - Add form validation. In the third iteration, we add basic form validation. We prevent people from submitting a form without completing required form fields. We also validate email addresses and phone numbers.
- Iteration #4 - Make the application loosely coupled. In this fourth iteration, we take advantage of several software design patterns to make it easier to maintain and modify the Contact Manager application. For example, we refactor our application to use the Repository pattern and the Dependency Injection pattern.
- Iteration #5 - Create unit tests. In the fifth iteration, we make our application easier to maintain and modify by adding unit tests. We mock our data model classes and build unit tests for our controllers and validation logic.
- Iteration #6 - Use test-driven development. In this sixth iteration, we add new functionality to our application by writing unit tests first and writing code against the unit tests. In this iteration, we add contact groups.
- Iteration #7 - Add Ajax functionality. In the seventh iteration, we improve the responsiveness and performance of our application by adding support for Ajax.

This Iteration

In this first iteration, we build the basic application. The goal is to build the Contact Manager in the fastest and simplest way possible. In later iterations, we improve the design of the application.

The Contact Manager application is a basic database-driven application. You can use the application to create new contacts, edit existing contacts, and delete contacts.

In this iteration, we complete the following steps:

1. ASP.NET MVC application
2. Create a database to store our contacts
3. Generate a model class for our database with the Microsoft Entity Framework
4. Create a controller action and view that enables us to list all of the contacts in the database
5. Create controller actions and a view that enables us to create a new contact in the database
6. Create controller actions and a view that enables us to edit an existing contact in the database
7. Create controller actions and a view that enables us to delete an existing contact in the database

Software Prerequisites

In ASP.NET MVC applications, you must have either Visual Studio 2008 or Visual Web Developer 2008 installed on your computer (Visual Web Developer is a free version of Visual Studio that does not include all of the advanced features of Visual Studio). You can download either the trial version of Visual Studio 2008 or Visual Web Developer from the following address:

https://www.asp.net/downloads/essential/

> **NOTE**
> For ASP.NET MVC applications with Visual Web Developer, you must have Visual Web Developer Service Pack 1 installed. Without Service Pack 1, you cannot create Web Application Projects.

ASP.NET MVC framework. You can download the ASP.NET MVC framework from the following address:

https://www.asp.net/mvc

In this tutorial, we use the Microsoft Entity Framework to access a database. The Entity Framework is included with .NET Framework 3.5 Service Pack 1. You can download this service pack from the following location:

https://www.microsoft.com/downloads/details.aspx?familyid=ab99342f-5d1a-413d-8319-81da479ab0d7&displaylang=en

As an alternative to performing each of these downloads one by one, you can take advantage of the Web Platform Installer (Web PI). You can download the Web PI from the following address:

https://www.asp.net/downloads/essential/

ASP.NET MVC Project

ASP.NET MVC Web Application Project. Launch Visual Studio and select the menu option **File, New Project**. The **New Project** dialog appears (see Figure 1). Select the **Web** project type and the **ASP.NET MVC Web Application** template. Name your new project *ContactManager* and click the OK button.

Make sure that you have .NET Framework 3.5 selected from the dropdown list at the top right of the **New Project** dialog. Otherwise, the ASP.NET MVC Web Application template won't appear.

Figure 01: The New Project dialog(Click to view full-size image)

ASP.NET MVC application, the **Create Unit Test Project** dialog appears. You can use this dialog to indicate that you want to create and add a unit test project to your solution when you create your ASP.NET MVC application. Although we won't be building unit tests in this iteration, you should select the option **Yes, create a unit test project** because we plan to add unit tests in a later iteration. Adding a Test project when you first create a new ASP.NET MVC project is much easier than adding a Test project after the ASP.NET MVC project has been created.

> **NOTE**
>
> Because Visual Web Developer does not support Test projects, you do not get the Create Unit Test Project dialog when using Visual Web Developer.

Figure 02: The Create Unit Test Project dialog (Click to view full-size image)

ASP.NET MVC application appears in the Visual Studio Solution Explorer window (see Figure 3). If you don t see the Solution Explorer window then you can open this window by selecting the menu option **View, Solution Explorer**. Notice that the solution contains two projects: the ASP.NET MVC project and the Test project. The ASP.NET MVC project is named ContactManager and the Test project is named ContactManager.Tests.

Figure 03: The Solution Explorer window (Click to view full-size image)

Deleting the Project Sample Files

The ASP.NET MVC project template includes sample files for controllers and views. Before creating a new ASP.NET MVC application, you should delete these files. You can delete files and folders in the Solution Explorer window by right-clicking a file or folder and selecting the menu option **Delete**.

You need to delete the following files from the ASP.NET MVC project:

- \Controllers\HomeController.cs
- \Views\Home\About.aspx
- \Views\Home\Index.aspx

And, you need to delete the following file from the Test project:

\Controllers\HomeControllerTest.cs

Creating the Database

The Contact Manager application is a database-driven web application. We use a database to store the contact information.

The ASP.NET MVC framework with any modern database including Microsoft SQL Server, Oracle, MySQL, and IBM DB2 databases. In this tutorial, we use a Microsoft SQL Server database. When you install Visual Studio, you are provided with the option of installing Microsoft SQL Server Express which is a free version of the Microsoft SQL Server database.

Create a new database by right-clicking the App_Data folder in the Solution Explorer window and selecting the menu option **Add, New Item**. In the **Add New Item** dialog, select the **Data** category and the **SQL Server Database** template (see Figure 4). Name the new database ContactManagerDB.mdf and click the OK button.

Figure 04: Creating a new Microsoft SQL Server Express database (Click to view full-size image)

After you create the new database, the database appears in the App_Data folder in the Solution Explorer window. Double-click the ContactManager.mdf file to open the Server Explorer window and connect to the database.

> **NOTE**
>
> The Server Explorer window is called the Database Explorer window in the case of Microsoft Visual Web Developer.

You can use the Server Explorer window to create new database objects such as database tables, views, triggers, and stored procedures. Right-click the Tables folder and select the menu option **Add New Table**. The Database Table Designer appears (see Figure 5).

Figure 05: The Database Table Designer (Click to view full-size image)

We need to create a table that contains the following columns:

COLUMN NAME	DATA TYPE	ALLOW NULLS
Id	int	false
FirstName	nvarchar(50)	false
LastName	nvarchar(50)	false
Phone	nvarchar(50)	false

COLUMN NAME	DATA TYPE	ALLOW NULLS
Email	nvarchar(255)	false

The first column, the Id column, is special. You need to mark the Id column as an Identity column and a Primary Key column. You indicate that a column is an Identity column by expanding Column Properties (look at the bottom of Figure 6) and scrolling down to the Identity Specification property. Set the **(Is Identity)** property to the value **Yes**.

You mark a column as a Primary Key column by selecting the column and clicking the button with the icon of a key. After a column is marked as a Primary Key column, an icon of a key appears next to the column (see Figure 6).

After you finish creating the table, click the Save button (the button with an icon of a floppy) to save the new table. Give your new table the name *Contacts*.

After finish creating the Contacts database table, you should add some records to the table. Right-click the Contacts table in the Server Explorer window and select the menu option **Show Table Data**. Enter one or more contacts in the grid that appears.

Creating the Data Model

The ASP.NET MVC application consists of Models, Views, and Controllers. We start by creating a Model class that represents the Contacts table that we created in the previous section.

In this tutorial, we use the Microsoft Entity Framework to generate a model class from the database automatically.

> **NOTE**
> The ASP.NET MVC framework is not tied to the Microsoft Entity Framework in any way. You can use ASP.NET MVC with alternative database access technologies including NHibernate, LINQ to SQL, or ADO.NET.

Follow these steps to create the data model classes:

1. Right-click the Models folder in the Solution Explorer window and select **Add, New Item**. The **Add New Item** dialog appears (see Figure 6).
2. Select the **Data** category and the **ADO.NET Entity Data Model** template. Name your data model *ContactManagerModel.edmx* and click the **Add** button. The Entity Data Model wizard appears (see Figure 7).
3. In the **Choose Model Contents** step, select **Generate from database** (see Figure 7).
4. In the **Choose Your Data Connection** step, select the ContactManagerDB.mdf database and enter the name *ContactManagerDBEntities* for the Entity Connection Settings (see Figure 8).
5. In the **Choose Your Database Objects** step, select the checkbox labeled Tables (see Figure 9). The data model will include all tables contained in your database (there is just one, the Contacts table). Enter the namespace *Models*. Click the Finish button to complete the wizard.

Figure 06: The Add New Item dialog (Click to view full-size image)

Figure 07: Choose Model Contents (Click to view full-size image)

Figure 08: Choose Your Data Connection (Click to view full-size image)

Figure 09: Choose Your Database Objects (Click to view full-size image)

After you complete the Entity Data Model Wizard, the Entity Data Model Designer appears. The designer displays a class that corresponds to each table being modeled. You should see one class named Contacts.

The Entity Data Model wizard generates class names based on database table names. You almost always need to change the name of the class generated by the wizard. Right-click the Contacts class in the designer and select the menu option **Rename**. Change the name of the class from Contacts (plural) to Contact (singular). After you change the class name, the class should appear like Figure 10.

Figure 10: The Contact class (Click to view full-size image)

At this point, we have created our database model. We can use the Contact class to represent a particular contact record in our database.

Creating the Home Controller

The next step is to create our Home controller. The Home controller is the default controller invoked in an ASP.NET MVC application.

Create the Home controller class by right-clicking the Controllers folder in the Solution Explorer window and selecting the menu option **Add, Controller** (see Figure 11). Notice the checkbox labeled **Add action methods for Create, Update, and Details scenarios**. Make sure that this checkbox is checked before clicking the **Add** button.

Figure 11: Adding the Home controller (Click to view full-size image)

When you create the Home controller, you get the class in Listing 1.

Listing 1 - Controllers\HomeController.cs

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using System.Web.Mvc;
using System.Web.Mvc.Ajax;

namespace ContactManager.Controllers
{
    public class HomeController : Controller
    {
        //
        // GET: /Home/

        public ActionResult Index()
        {
            return View();
        }

        //
        // GET: /Home/Details/5

        public ActionResult Details(int id)
        {
            return View();
        }

        //
        // GET: /Home/Create

        public ActionResult Create()
        {
            return View();
        }

        //
        // POST: /Home/Create

        [AcceptVerbs(HttpVerbs.Post)]
        public ActionResult Create(FormCollection collection)
        {
            try
            {
                // TODO: Add insert logic here

                return RedirectToAction("Index");
            }
            catch
            {
                return View();
            }
```

```
        }

        //
        // GET: /Home/Edit/5

        public ActionResult Edit(int id)
        {
            return View();
        }

        //
        // POST: /Home/Edit/5

        [AcceptVerbs(HttpVerbs.Post)]
        public ActionResult Edit(int id, FormCollection collection)
        {
            try
            {
                // TODO: Add update logic here

                return RedirectToAction("Index");
            }
            catch
            {
                return View();
            }
        }
    }
}
```

Listing the Contacts

In order to display the records in the Contacts database table, we need to create an Index() action and an Index view.

The Home controller already contains an Index() action. We need to modify this method so that it looks like Listing 2.

Listing 2 - Controllers\HomeController.cs

```
public class HomeController : Controller
{

    private ContactManagerDBEntities _entities = new ContactManagerDBEntities();

    //
    // GET: /Home/

    public ActionResult Index()
    {
        return View(_entities.ContactSet.ToList());
    }
…
```

Notice that the Home controller class in Listing 2 contains a private field named _entities. The _entities field represents the entities from the data model. We use the _entities field to communicate with the database.

The Index() method returns a view that represents all of the contacts from the Contacts database table. The expression _entities.ContactSet.ToList() returns the list of contacts as a generic list.

Now that we ve created the Index controller, we next need to create the Index view. Before creating the Index view, compile your application by selecting the menu option **Build, Build Solution**. You should always compile your project before adding a view in order for the list of model classes to be displayed in the **Add View** dialog.

You create the Index view by right-clicking the Index() method and selecting the menu option **Add View** (see Figure 12). Selecting this menu option opens the **Add View** dialog (see Figure 13).

Figure 12: Adding the Index view (Click to view full-size image)

In the **Add View** dialog, check the checkbox labeled **Create a strongly-typed view**. Select the View data class ContactManager.Models.Contact and the View content List. Selecting these options generates a view that displays a list of Contact records.

Figure 13: The Add View dialog (Click to view full-size image)

When you click the **Add** button, the Index view in Listing 3 is generated. Notice the <%@ Page %> directive that appears at the top of the file. The Index view inherits from the ViewPage<IEnumerable<ContactManager.Models.Contact>> class. In other words, the Model class in the view represents a list of Contact entities.

The body of the Index view contains a foreach loop that iterates through each of the contacts represented by the Model class. The value of each property of the Contact class is displayed within an HTML table.

Listing 3 - Views\Home\Index.aspx (unmodified)

```
<%@ Page Title="" Language="C#" MasterPageFile="~/Views/Shared/Site.Master"
Inherits="System.Web.Mvc.ViewPage<IEnumerable<ContactManager.Models.Contact>>" %>

<asp:Content ID="Content1" ContentPlaceHolderID="head" runat="server">
<title>Index</title>
</asp:Content>

<asp:Content ID="Content2" ContentPlaceHolderID="MainContent" runat="server">

    <h2>Index</h2>

    <table>
        <tr>
            <th></th>
            <th>
                Id
            </th>
            <th>
                FirstName
            </th>
            <th>
                LastName
            </th>
            <th>
                Phone
            </th>
            <th>
                Email
            </th>
        </tr>

    <% foreach (var item in Model) { %>

        <tr>
            <td>
                <%= Html.ActionLink("Edit", "Edit", new { id=item.Id  }) %> |
                <%= Html.ActionLink("Details", "Details", new { id=item.Id  })%>
            </td>
            <td>
                <%= Html.Encode(item.Id) %>
            </td>
            <td>
                <%= Html.Encode(item.FirstName) %>
            </td>
            <td>
                <%= Html.Encode(item.LastName) %>
            </td>
            <td>
                <%= Html.Encode(item.Phone) %>
            </td>
            <td>
                <%= Html.Encode(item.Email) %>
            </td>
        </tr>

    <% } %>

    </table>

    <p>
        <%= Html.ActionLink("Create New", "Create") %>
    </p>

</asp:Content>
```

We need to make one modification to the Index view. Because we are not creating a Details view, we can remove

the Details link. Find and remove the following code from the Index view:

{ id=item.Id })%>

After you modify the Index view, you can run the Contact Manager application. Select the menu option Debug, Start Debugging or simply press F5. The first time you run the application, you get the dialog in Figure 14. Select the option **Modify the Web.config file to enable debugging** and click the OK button.

Figure 14: Enabling debugging (Click to view full-size image)

The Index view is returned by default. This view lists all of the data from the Contacts database table (see Figure 15).

Figure 15: The Index view (Click to view full-size image)

Notice that the Index view includes a link labeled Create New at the bottom of the view. In the next section, you learn how to create new contacts.

Creating New Contacts

To enable users to create new contacts, we need to add two Create() actions to the Home controller. We need to create one Create() action that returns an HTML form for creating a new contact. We need to create a second Create() action that performs the actual database insert of the new contact.

The new Create() methods that we need to add to the Home controller are contained in Listing 4.

Listing 4 - Controllers\HomeController.cs (with Create methods)

```
//
// GET: /Home/Create

public ActionResult Create()
{
    return View();
}

//
// POST: /Home/Create

[AcceptVerbs(HttpVerbs.Post)]
public ActionResult Create([Bind(Exclude = "Id")] Contact contactToCreate)
{
    if (!ModelState.IsValid)
        return View();

    try
    {
        _entities.AddToContactSet(contactToCreate);
        _entities.SaveChanges();
        return RedirectToAction("Index");
    }
    catch
    {
        return View();
    }
}
```

The first Create() method can be invoked with an HTTP GET while the second Create() method can be invoked only by an HTTP POST. In other words, the second Create() method can be invoked only when posting an HTML form. The first Create() method simply returns a view that contains the HTML form for creating a new contact. The second Create() method is much more interesting: it adds the new contact to the database.

Notice that the second Create() method has been modified to accept an instance of the Contact class. The form values posted from the HTML form are bound to this Contact class by the ASP.NET MVC framework automatically. Each form field from the HTML Create form is assigned to a property of the Contact parameter.

Notice that the Contact parameter is decorated with a [Bind] attribute. The [Bind] attribute is used to exclude the Contact Id property from binding. Because the Id property represents an Identity property, we don t want to set the Id property.

In the body of the Create() method, the Entity Framework is used to insert the new Contact into the database. The new Contact is added to the existing set of Contacts and the SaveChanges() method is called to push these changes back to the underlying database.

You can generate an HTML form for creating new Contacts by right-clicking either of the two Create() methods and selecting the menu option **Add View** (see Figure 16).

Figure 16: Adding the Create view (Click to view full-size image)

In the **Add View** dialog, select the **ContactManager.Models.Contact** class and the **Create** option for view content (see Figure 17). When you click the **Add** button, a Create view is generated automatically.

Figure 17: Seeing a page explode (Click to view full-size image)

The Create view contains form fields for each of the properties of the Contact class. The code for the Create view is included in Listing 5.

Listing 5 - Views\Home\Create.aspx

```
<%@ Page Title="" Language="C#" MasterPageFile="~/Views/Shared/Site.Master"
Inherits="System.Web.Mvc.ViewPage<ContactManager.Models.Contact>" %>

<asp:Content ID="Content1" ContentPlaceHolderID="head" runat="server">
<title>Create</title>
</asp:Content>

<asp:Content ID="Content2" ContentPlaceHolderID="MainContent" runat="server">

    <h2>Create</h2>

    <%= Html.ValidationSummary() %>

    <% using (Html.BeginForm()) {%>

        <fieldset>
            <legend>Fields</legend>
            <p>
                <label for="FirstName">FirstName:</label>
                <%= Html.TextBox("FirstName") %>
                <%= Html.ValidationMessage("FirstName", "*") %>
            </p>
            <p>
                <label for="LastName">LastName:</label>
                <%= Html.TextBox("LastName") %>
                <%= Html.ValidationMessage("LastName", "*") %>
            </p>
            <p>
                <label for="Phone">Phone:</label>
                <%= Html.TextBox("Phone") %>
                <%= Html.ValidationMessage("Phone", "*") %>
            </p>
            <p>
                <label for="Email">Email:</label>
                <%= Html.TextBox("Email") %>
                <%= Html.ValidationMessage("Email", "*") %>
            </p>
            <p>
                <input type="submit" value="Create" />
            </p>
        </fieldset>

    <% } %>

    <div>
        <%=Html.ActionLink("Back to List", "Index") %>
    </div>

</asp:Content>
```

After you modify the Create() methods and add the Create view, you can run the Contact Manger application and create new contacts. Click the **Create New** link that appears in the Index view to navigate to the Create view. You should see the view in Figure 18.

Figure 18: The Create View (Click to view full-size image)

Editing Contacts

Adding the functionality for editing a contact record is very similar to adding the functionality for creating new contact records. First, we need to add two new Edit methods to the Home controller class. These new Edit() methods are contained in Listing 6.

Listing 6 - Controllers\HomeController.cs (with Edit methods)

```
//
// GET: /Home/Edit/5

public ActionResult Edit(int id)
{
    var contactToEdit = (from c in _entities.ContactSet
                         where c.Id == id
                         select c).FirstOrDefault();

    return View(contactToEdit);
}

//
// POST: /Home/Edit/5

[AcceptVerbs(HttpVerbs.Post)]
public ActionResult Edit(Contact contactToEdit)
{
    if (!ModelState.IsValid)
        return View();

    try
    {
        var originalContact = (from c in _entities.ContactSet
                               where c.Id == contactToEdit.Id
                               select c).FirstOrDefault();
        _entities.ApplyPropertyChanges(originalContact.EntityKey.EntitySetName, contactToEdit);
        _entities.SaveChanges();
        return RedirectToAction("Index");
    }
    catch
    {
        return View();
    }
}
}
```

The first Edit() method is invoked by an HTTP GET operation. An Id parameter is passed to this method which represents the Id of the contact record being edited. The Entity Framework is used to retrieve a contact that matches the Id. A view that contains an HTML form for editing a record is returned.

The second Edit() method performs the actual update to the database. This method accepts an instance of the Contact class as a parameter. The ASP.NET MVC framework binds the form fields from the Edit form to this class automatically. Notice that you don t include the[Bind] attribute when editing a Contact (we need the value of the Id property).

The Entity Framework is used to save the modified Contact to the database. The original Contact must be retrieved from the database first. Next, the Entity Framework ApplyPropertyChanges() method is called to record the changes to the Contact. Finally, the Entity Framework SaveChanges() method is called to persist the changes to the underlying database.

You can generate the view that contains the Edit form by right-clicking the Edit() method and selecting the menu option Add View. In the Add View dialog, select the **ContactManager.Models.Contact** class and the **Edit** view content (see Figure 19).

Figure 19: Adding an Edit View (Click to view full-size image)

When you click the Add button, a new Edit view is generated automatically. The HTML form that is generated contains fields that correspond to each of the properties of the Contact class (see Listing 7).

Listing 7 - Views\Home\Edit.aspx

```
<%@ Page Title="" Language="C#" MasterPageFile="~/Views/Shared/Site.Master"
Inherits="System.Web.Mvc.ViewPage<ContactManager.Models.Contact>" %>

<asp:Content ID="Content1" ContentPlaceHolderID="head" runat="server">
<title>Edit</title>
</asp:Content>

<asp:Content ID="Content2" ContentPlaceHolderID="MainContent" runat="server">

    <h2>Edit</h2>

    <%= Html.ValidationSummary() %>

    <% using (Html.BeginForm()) {%>

        <fieldset>
            <legend>Fields</legend>
            <p>
                <label for="FirstName">FirstName:</label>
                <%= Html.TextBox("FirstName") %>
                <%= Html.ValidationMessage("FirstName", "*") %>
            </p>
            <p>
                <label for="LastName">LastName:</label>
                <%= Html.TextBox("LastName") %>
                <%= Html.ValidationMessage("LastName", "*") %>
            </p>
            <p>
                <label for="Phone">Phone:</label>
                <%= Html.TextBox("Phone") %>
                <%= Html.ValidationMessage("Phone", "*") %>
            </p>
            <p>
                <label for="Email">Email:</label>
                <%= Html.TextBox("Email") %>
                <%= Html.ValidationMessage("Email", "*") %>
            </p>
            <p>
                <input type="submit" value="Save" />
            </p>
        </fieldset>

    <% } %>

    <div>
        <%=Html.ActionLink("Back to List", "Index") %>
    </div>

</asp:Content>
```

Deleting Contacts

If you want to delete contacts then you need to add two Delete() actions to the Home controller class. The first Delete() action displays a delete confirmation form. The second Delete() action performs the actual delete.

> **NOTE**
>
> Later, in Iteration #7, we modify the Contact Manager so that it supports a one step Ajax delete.

The two new Delete() methods are contained in Listing 8.

Listing 8 - Controllers\HomeController.cs (Delete methods)

```
//
// GET: /Home/Delete/5

public ActionResult Delete(int id)
{
    var contactToDelete = (from c in _entities.ContactSet
                           where c.Id == id
                           select c).FirstOrDefault();

    return View(contactToDelete);
}

//
// POST: /Home/Delete/5

[AcceptVerbs(HttpVerbs.Post)]
public ActionResult Delete(Contact contactToDelete)
{
    try
    {
        var originalContact = (from c in _entities.ContactSet
                               where c.Id == contactToDelete.Id
                               select c).FirstOrDefault();

        _entities.DeleteObject(originalContact);
        _entities.SaveChanges();
        return RedirectToAction("Index");
    }
    catch
    {
        return View();
    }
}
```

The first Delete() method returns a confirmation form for deleting a contact record from the database (see Figure20). The second Delete() method performs the actual delete operation against the database. After the original contact has been retrieved from the database, the Entity Framework DeleteObject() and SaveChanges() methods are called to perform the database delete.

Figure 20: The delete confirmation view (Click to view full-size image)

We need to modify the Index view so that it contains a link for deleting contact records (see Figure 21). You need to add the following code to the same table cell that contains the Edit link:

Html.ActionLink({ id=item.Id }) %>

Figure 21: Index view with Edit link (Click to view full-size image)

Next, we need to create the delete confirmation view. Right-click the Delete() method in the Home controller class and select the menu option Add View. The Add View dialog appears (see Figure 22).

Unlike in the case of the List, Create, and Edit views, the Add View dialog does not contain an option to create a Delete view. Instead, select the **ContactManager.Models.Contact** data class and the **Empty** view content. Selecting the Empty view content option will require us to create the view ourselves.

Figure 22: Adding the delete confirmation view (Click to view full-size image)

The content of the Delete view is contained in Listing 9. This view contains a form that confirms whether or not a particular contact should be deleted (see Figure 21).

Listing 9 - Views\Home\Delete.aspx

```
<%@ Page Title="" Language="C#" MasterPageFile="~/Views/Shared/Site.Master"
Inherits="System.Web.Mvc.ViewPage<ContactManager.Models.Contact>" %>

<asp:Content ID="Content1" ContentPlaceHolderID="head" runat="server">
<title>Delete</title>
</asp:Content>

<asp:Content ID="Content2" ContentPlaceHolderID="MainContent" runat="server">

    <h2>Delete</h2>

    <p>
    Are you sure that you want to delete the entry for
    <%= Model.FirstName %> <%= Model.LastName %>?
    </p>

    <% using (Html.BeginForm(new { Id = Model.Id }))
       { %>
       <p>
            <input type="submit" value="Delete" />
        </p>
    <% } %>

    <div>
        <%=Html.ActionLink("Back to List", "Index") %>
    </div>

</asp:Content>
```

Changing the Name of the Default Controller

It might bother you that the name of our controller class for working with contacts is named the HomeController class. Shouldn't the controller be named ContactController?

This issue is easy enough to fix. First, we need to refactor the name of the Home controller. Open the HomeController class in the Visual Studio Code Editor, right click the name of the class and select the menu option **Refactor, Rename**. Selecting this menu option opens the Rename dialog.

Figure 23: Refactoring a controller name (Click to view full-size image)

Figure 24: Using the Rename dialog (Click to view full-size image)

If you rename your controller class, Visual Studio will update the name of the folder in the Views folder as well. Visual Studio will rename the \Views\Home folder to the \Views\Contact folder.

After you make this change, your application will no longer have a Home controller. When you run your application, you'll get the error page in Figure 25.

Figure 25: No default controller (Click to view full-size image)

We need to update the default route in the Global.asax file to use the Contact controller instead of the Home controller. Open the Global.asax file and modify the default controller used by the default route (see Listing 10).

Listing 10 - Global.asax.cs

```
using System.Web.Mvc;
using System.Web.Routing;

namespace ContactManager
{
    public class MvcApplication : System.Web.HttpApplication
    {
        public static void RegisterRoutes(RouteCollection routes)
        {
            routes.IgnoreRoute("{resource}.axd/{*pathInfo}");

            routes.MapRoute(
                "Default",                                          // Route name
                "{controller}/{action}/{id}",                       // URL with parameters
                new { controller = "Contact", action = "Index", id = "" }  // Parameter defaults
            );

        }

        protected void Application_Start()
        {
            RegisterRoutes(RouteTable.Routes);
        }
    }
}
```

After you make these changes, the Contact Manager will run correctly. Now, it will use the Contact controller class as the default controller.

Summary

In this first iteration, we created a basic Contact Manager application in the fastest way possible. We took advantage of Visual Studio to generate the initial code for our controllers and views automatically. We also took advantage of the Entity Framework to generate our database model classes automatically.

Currently, we can list, create, edit, and delete contact records with the Contact Manager application. In other words, we can perform all of the basic database operations required by a database-driven web application.

Unfortunately, our application has some problems. First and I hesitate to admit this, the Contact Manager application is not the most attractive application. It needs some design work. In the next iteration, we'll look at how we can change the default view master page and cascading style sheet to improve the appearance of the application.

Second, we have not implemented any form validation. For example, there is nothing to prevent you from submitting the Create contact form without entering values for any of the form fields. Furthermore, you can enter invalid phone numbers and email addresses. We start to tackle the problem of form validation in iteration #3.

Finally, and most importantly, the current iteration of the Contact Manager application cannot be easily modified or maintained. For example, the database access logic is baked right into the controller actions. This means that we cannot modify our data access code without modifying our controllers. In later iterations, we explore software design patterns that we can implement to make the Contact Manager more resilient to change.

> In this iteration, we improve the appearance of the application by modifying the default ASP.NET MVC view master page and cascading style sheet.

Building a Contact Management ASP.NET MVC Application (C#)

In this series of tutorials, we build an entire Contact Management application from start to finish. The Contact Manager application enables you to store contact information - names, phone numbers and email addresses - for a list of people.

We build the application over multiple iterations. With each iteration, we gradually improve the application. The goal of this multiple iteration approach is to enable you to understand the reason for each change.

- Iteration #1 - Create the application. In the first iteration, we create the Contact Manager in the simplest way possible. We add support for basic database operations: Create, Read, Update, and Delete (CRUD).
- Iteration #2 - Make the application look nice. In this iteration, we improve the appearance of the application by modifying the default ASP.NET MVC view master page and cascading style sheet.
- Iteration #3 - Add form validation. In the third iteration, we add basic form validation. We prevent people from submitting a form without completing required form fields. We also validate email addresses and phone numbers.
- Iteration #4 - Make the application loosely coupled. In this fourth iteration, we take advantage of several software design patterns to make it easier to maintain and modify the Contact Manager application. For example, we refactor our application to use the Repository pattern and the Dependency Injection pattern.
- Iteration #5 - Create unit tests. In the fifth iteration, we make our application easier to maintain and modify by adding unit tests. We mock our data model classes and build unit tests for our controllers and validation logic.
- Iteration #6 - Use test-driven development. In this sixth iteration, we add new functionality to our application by writing unit tests first and writing code against the unit tests. In this iteration, we add contact groups.
- Iteration #7 - Add Ajax functionality. In the seventh iteration, we improve the responsiveness and performance of our application by adding support for Ajax.

This Iteration

The goal of this iteration is to improve the appearance of the Contact Manager application. Currently, the Contact Manager uses the default ASP.NET MVC view master page and cascading style sheet (see Figure 1). These don t look bad, but I don t want the Contact Manager to look just like every other ASP.NET MVC website. I want to replace these files with custom files.

Figure 01: The default appearance of an ASP.NET MVC Application (Click to view full-size image)

In this iteration, I discuss two approaches to improving the visual design of our application. First, I show you how to take advantage of the ASP.NET MVC Design gallery to download a free ASP.NET MVC design template. The ASP.NET MVC Design gallery enables you to create a professional web application without doing any work.

I decided to not use a template from the ASP.NET MVC Design gallery for the Contact Manager application. Instead, I had a custom design created by a professional design firm. In the second part of this tutorial, I explain how I worked with a professional design company to create the final ASP.NET MVC design.

The ASP.NET MVC Design Gallery

The ASP.NET MVC Design Gallery is a free resource provided by Microsoft. The ASP.NET MVC Gallery is located at the following address:

https://www.asp.net/mvc/gallery

The ASP.NET MVC Design Gallery hosts a collection of free website designs that were created specifically for using in an ASP.NET MVC project. Designs are uploaded by members of the community. Visitors to the Gallery can vote for their favorite designs (see Figure 2).

Figure 02: The ASP.NET MVC Design Gallery (Click to view full-size image)

As I write this tutorial, the most popular design in the gallery is a design named October by David Hauser. You can use this design for an ASP.NET MVC project by completing the following steps:

1. Click the **Download** button to download the October.zip file to your computer.
2. Right-click the downloaded October.zip file and click the **Unblock** button (see Figure 3).
3. Unzip the file to a folder named October.
4. Select all of the files from the DesignTemplate folder contained in the October folder, right-click the files, and select the menu option **Copy**.

5. Right-click the ContactManager project node in the Visual Studio Solution Explorer window and select the menu option **Paste** (see Figure 4).
6. Select the Visual Studio menu option **Edit, Find and Replace, Quick Replace** and replace *[MyProjectName]* with *ContactManager* (see Figure 5).

Figure 03: Unblocking a file downloaded from the web (Click to view full-size image)

Figure 04: Overwriting files in the Solution Explorer (Click to view full-size image)

Figure 05: Replacing [ProjectName] with ContactManager (Click to view full-size image)

After you complete these steps, your web application will use the new design. The page in Figure 6 illustrates the appearance of the Contact Manager application with the October design.

Figure 06: ContactManager with the October template (Click to view full-size image)

Creating a Custom ASP.NET MVC Design

The ASP.NET MVC Design Gallery has a good selection of different design styles. The Gallery provides you with a painless way to customize the appearance of your ASP.NET MVC applications. And, of course, the Gallery has the big advantage of being completely free.

However, you might need to create a completely unique design for your website. In that case, it makes sense to work with a website design company. I decided to take this approach for the design for the Contact Manager application.

I zipped up the Contact Manager from Iteration #1 and sent the project to the design company. They did not own Visual Studio (shame on them!), but that didn't present a problem. They were able to download Microsoft Visual Web Developer for free from the https://www.asp.net website and open the Contact Manager application in Visual Web Developer. In a couple of days, they had produced the design in Figure 7.

Figure 07: The ASP.NET MVC Contact Manager Design (Click to view full-size image)

The new design consisted of two main files: a new cascading style sheet file and a new view master page file. A view master page contains the layout and shared content for views in an ASP.NET MVC application. For example, the view master page includes the header, navigation tabs, and footer that appear in Figure 7. I overwrote the existing Site.Master view master page in the Views\Shared folder with the new Site.Master file from the design company,

The design company also created a new cascading style sheet and set of images. I placed these new files in the Content folder and overwrote the existing Site.css file. You should place all static content in the Content folder.

Notice that the new design for the Contact Manager includes images for editing and deleting contacts. An Edit and Delete image appear next to each contact in the HTML table of contacts.

Originally, these links that were rendered with the HTML.ActionLink() helper like this:

```
<td>
    <%= Html.ActionLink("Edit", "Edit", new { id=item.Id  }) %> |
    <%= Html.ActionLink("Delete", "Delete", new { id=item.Id  }) %>
</td>
```

The Html.ActionLink() method does not support images (the method HTML encodes the link text for security reasons). Therefore, I replaced the calls to Html.ActionLink() with calls to Url.Action() like this:

```
<td class="actions edit">
    <a href='<%= Url.Action("Edit", new {id=item.Id}) %>'><img src="../../Content/Edit.png" alt="Edit" /></a>
</td>
<td class="actions delete">
    <a href='<%= Url.Action("Delete", new {id=item.Id}) %>'><img src="../../Content/Delete.png" alt="Delete"
/></a>
</td>
```

The Html.ActionLink() method renders an entire HTML hyperlink. The Url.Action() method, on the other hand, renders just the URL without the <a> tag.

Notice, furthermore, that the new design includes both selected and unselected tabs. For example, in Figure 8, the **Create New Contact** tab is selected and the **My Contacts** tab is not selected.

Figure 08: Selected and unselected tabs(Click to view full-size image)

To support rendering both selected and unselected tabs, I created a custom HTML helper named the MenuItemHelper. This helper method renders either a <li> tag or a <li class="selected"> tag depending on whether the current controller and action corresponds to the controller and action name passed to the helper. The code for the MenuItemHelper is contained in Listing 1.

Listing 1 - Helpers\MenuItemHelper.cs

```
using System;
using System.Web.Mvc;
using System.Web.Mvc.Html;

namespace Helpers
{
    /// <summary>
    /// This helper method renders a link within an HTML LI tag.
    /// A class="selected" attribute is added to the tag when
    /// the link being rendered corresponds to the current
    /// controller and action.
    ///
    /// This helper method is used in the Site.Master View
    /// Master Page to display the website menu.
    /// </summary>
    public static class MenuItemHelper
    {
        public static string MenuItem(this HtmlHelper helper, string linkText, string actionName, string
controllerName)
        {
            string currentControllerName = (string)helper.ViewContext.RouteData.Values["controller"];
            string currentActionName = (string)helper.ViewContext.RouteData.Values["action"];

            var builder = new TagBuilder("li");

            // Add selected class
            if (currentControllerName.Equals(controllerName, StringComparison.CurrentCultureIgnoreCase) &&
currentActionName.Equals(actionName, StringComparison.CurrentCultureIgnoreCase))
                builder.AddCssClass("selected");

            // Add link
            builder.InnerHtml = helper.ActionLink(linkText, actionName, controllerName);

            // Render Tag Builder
            return builder.ToString(TagRenderMode.Normal);
        }

    }
}
```

The MenuItemHelper uses the TagBuilder class internally to build the <li> HTML tag. The TagBuilder class is a very useful utility class that you can use whenever you need to build up a new HTML tag. It includes methods for adding attributes, adding CSS classes, generating Ids, and modifying the tag s inner HTML.

Summary

In this iteration, we improved the visual design of our ASP.NET MVC application. First, you were introduced to the ASP.NET MVC Design Gallery. You learned how to download free design templates from the ASP.NET MVC Design Gallery that you can use in your ASP.NET MVC applications.

Next, we discussed how you can create a custom design by modifying the default cascading style sheet file and master view page file. In order to support the new design, we had to make some minor changes to our Contact Manager application. For example, we added a new HTML helper named the MenuItemHelper that displays selected and unselected tabs.

In the next iteration, we tackle the very important subject of validation. We add validation code to our application so that a user cannot create a new contact without supplying required values such as a person s first and last name.

Iteration #3 – Add form validation (C#)

For example, we refactor our application to use the Repository pattern and the Dependency Injection pattern.
- Iteration #5 - Create unit tests. In the fifth iteration, we make our application easier to maintain and modify by adding unit tests. We mock our data model classes and build unit tests for our controllers and validation logic.
- Iteration #6 - Use test-driven development. In this sixth iteration, we add new functionality to our application by writing unit tests first and writing code against the unit tests. In this iteration, we add contact groups.
- Iteration #7 - Add Ajax functionality. In the seventh iteration, we improve the responsiveness and performance of our application by adding support for Ajax.

This Iteration

In this second iteration of the Contact Manager application, we add basic form validation. We prevent people from submitting a contact without entering values for required form fields. We also validate phone numbers and email addresses (see Figure 1).

Figure 01: A form with validation (Click to view full-size image)

In this iteration, we add the validation logic directly to the controller actions. In general, this is not the recommended way to add validation to an ASP.NET MVC application. A better approach is to place an application s validation logic in a separate service layer. In the next iteration, we refactor the Contact Manager application to make the application more maintainable.

In this iteration, to keep things simple, we write all of the validation code by hand. Instead of writing the validation code ourselves, we could take advantage of a validation framework. For example, you can use the Microsoft Enterprise Library Validation Application Block (VAB) to implement the validation logic for your ASP.NET MVC application. To learn more about the Validation Application Block, see:

http://msdn.microsoft.com/library/dd203099.aspx

Adding Validation to the Create View

Let s start by adding validation logic to the Create view. Fortunately, because we generated the Create view with Visual Studio, the Create view already contains all of the necessary user interface logic to display validation messages. The Create view is contained in Listing 1.

Listing 1 - \Views\Contact\Create.aspx

```
<%@ Page Title="" Language="C#" MasterPageFile="~/Views/Shared/Site.Master"
Inherits="System.Web.Mvc.ViewPage<ContactManager.Models.Contact>" %>

<asp:Content ID="Content1" ContentPlaceHolderID="head" runat="server">
<title>Create</title>
</asp:Content>

<asp:Content ID="Content2" ContentPlaceHolderID="MainContent" runat="server">

    <%= Html.ValidationSummary() %>

    <% using (Html.BeginForm()) {%>

        <fieldset class="fields">
            <legend>Create New Contact</legend>
            <p>
                <label for="FirstName">First Name:</label>
                <%= Html.TextBox("FirstName") %>
                <%= Html.ValidationMessage("FirstName", "*") %>
            </p>
            <p>
                <label for="LastName">Last Name:</label>
                <%= Html.TextBox("LastName") %>
                <%= Html.ValidationMessage("LastName", "*") %>
            </p>
            <p>
                <label for="Phone">Phone:</label>
                <%= Html.TextBox("Phone") %>
                <%= Html.ValidationMessage("Phone", "*") %>
            </p>
            <p>
                <label for="Email">Email:</label>
                <%= Html.TextBox("Email") %>
                <%= Html.ValidationMessage("Email", "*") %>
            </p>
            <p class="submit">
                <input type="submit" value="Create" />
            </p>
        </fieldset>

    <% } %>

</asp:Content>
```

Notice the call to the Html.ValidationSummary() helper method that appears immediately above the HTML form. If there are validation error messages, then this method displays validation messages in a bulleted list.

Notice, furthermore, the calls to Html.ValidationMessage() that appear next to each form field. The ValidationMessage() helper displays an individual validation error message. In the case of Listing 1, an asterisk is displayed when there is a validation error.

Finally, the Html.TextBox() helper automatically renders a Cascading Style Sheet class when there is a validation error associated with the property displayed by the helper. The Html.TextBox() helper renders a class named **input-validation-error**.

When you create a new ASP.NET MVC application, a style sheet named Site.css is created in the Content folder automatically. This style sheet contains the following definitions for CSS classes related to the appearance of validation error messages:

```
.field-validation-error
{
    color: #ff0000;
}

.input-validation-error
{
    border: 1px solid #ff0000;
    background-color: #ffeeee;
}

.validation-summary-errors
{
    font-weight: bold;
    color: #ff0000;
}
```

The field-validation-error class is used to style the output rendered by the Html.ValidationMessage() helper. The input-validation-error class is used to style the textbox (input) rendered by the Html.TextBox() helper. The validation-summary-errors class is used to style the unordered list rendered by the Html.ValidationSummary() helper.

> **NOTE**
> You can modify the style sheet classes described in this section to customize the appearance of validation error messages.

Adding Validation Logic to the Create Action

Right now, the Create view never displays validation error messages because we have not written the logic to generate any messages. In order to display validation error messages, you need to add the error messages to ModelState.

> **NOTE**
> The UpdateModel() method adds error messages to ModelState automatically when there is an error assigning the value of a form field to a property. For example, if you attempt to assign the string "apple" to a BirthDate property that accepts DateTime values, then the UpdateModel() method adds an error to ModelState.

The modified Create() method in Listing 2 contains a new section that validates the properties of the Contact class before the new contact is inserted into the database.

Listing 2 - Controllers\ContactController.cs (Create with validation)

```
//
// POST: /Contact/Create

[AcceptVerbs(HttpVerbs.Post)]
public ActionResult Create([Bind(Exclude = "Id")] Contact contactToCreate)
{
    // Validation logic
    if (contactToCreate.FirstName.Trim().Length == 0)
        ModelState.AddModelError("FirstName", "First name is required.");
    if (contactToCreate.LastName.Trim().Length == 0)
        ModelState.AddModelError("LastName", "Last name is required.");
    if (contactToCreate.Phone.Length > 0 && !Regex.IsMatch(contactToCreate.Phone, @"((\(\d{3}\) ?)|(\d{3}-))?
\d{3}-\d{4}"))
        ModelState.AddModelError("Phone", "Invalid phone number.");
    if (contactToCreate.Email.Length > 0 && !Regex.IsMatch(contactToCreate.Email, @"^[\w-\.]+@([\w-]+\.)+[\w-]
{2,4}$"))
        ModelState.AddModelError("Email", "Invalid email address.");
    if (!ModelState.IsValid)
        return View();

    // Database logic
    try
    {
        _entities.AddToContactSet(contactToCreate);
        _entities.SaveChanges();
        return RedirectToAction("Index");
    }
    catch
    {
        return View();
    }
}
```

The validate section enforces four distinct validation rules:

- The FirstName property must have a length greater than zero (and it cannot consist solely of spaces)
- The LastName property must have a length greater than zero (and it cannot consist solely of spaces)
- If the Phone property has a value (has a length greater than 0) then the Phone property must match a regular expression.
- If the Email property has a value (has a length greater than 0) then the Email property must match a regular expression.

When there is a validation rule violation, an error message is added to ModelState with the help of the AddModelError() method. When you add a message to ModelState, you provide the name of a property and the text of a validation error message. This error message is displayed in the view by the Html.ValidationSummary() and Html.ValidationMessage() helper methods.

After the validation rules are executed, the IsValid property of ModelState is checked. The IsValid property returns false when any validation error messages have been added to ModelState. If validation fails, the Create form is redisplayed with the error messages.

> **NOTE**
>
> I got the regular expressions for validating the phone number and email address from the regular expression repository at *http://regexlib.com*

Adding Validation Logic to the Edit Action

The Edit() action updates a Contact. The Edit() action needs to perform exactly the same validation as the Create()

action. Instead of duplicating the same validation code, we should refactor the Contact controller so that both the Create() and Edit() actions call the same validation method.

The modified Contact controller class is contained in Listing 3. This class has a new ValidateContact() method that is called within both the Create() and Edit() actions.

Listing 3 - Controllers\ContactController.cs

```
using System.Linq;
using System.Text.RegularExpressions;
using System.Web.Mvc;
using ContactManager.Models;

namespace ContactManager.Controllers
{
    public class ContactController : Controller
    {
        private ContactManagerDBEntities _entities = new ContactManagerDBEntities();

        protected void ValidateContact(Contact contactToValidate)
        {
            if (contactToValidate.FirstName.Trim().Length == 0)
                ModelState.AddModelError("FirstName", "First name is required.");
            if (contactToValidate.LastName.Trim().Length == 0)
                ModelState.AddModelError("LastName", "Last name is required.");
            if (contactToValidate.Phone.Length > 0 && !Regex.IsMatch(contactToValidate.Phone, @"((\(\d{3}\)
?)|(\d{3}-))?\d{3}-\d{4}"))
                ModelState.AddModelError("Phone", "Invalid phone number.");
            if (contactToValidate.Email.Length > 0 && !Regex.IsMatch(contactToValidate.Email, @"^[\w-
\.]+@([\w-]+\.)+[\w-]{2,4}$"))
                ModelState.AddModelError("Email", "Invalid email address.");
        }

        public ActionResult Index()
        {
            return View(_entities.ContactSet.ToList());
        }

        public ActionResult Create()
        {
            return View();
        }

        [AcceptVerbs(HttpVerbs.Post)]
        public ActionResult Create([Bind(Exclude = "Id")] Contact contactToCreate)
        {
            // Validation logic
            ValidateContact(contactToCreate);
            if (!ModelState.IsValid)
                return View();

            // Database logic
            try
            {
                _entities.AddToContactSet(contactToCreate);
                _entities.SaveChanges();
                return RedirectToAction("Index");
            }
            catch
            {
                return View();
            }
        }

        public ActionResult Edit(int id)
        {
            var contactToEdit = (from c in _entities.ContactSet
```

```
                                where c.Id == id
                                select c).FirstOrDefault();

            return View(contactToEdit);
        }

        [AcceptVerbs(HttpVerbs.Post)]
        public ActionResult Edit(Contact contactToEdit)
        {
            ValidateContact(contactToEdit);
            if (!ModelState.IsValid)
                return View();

            try
            {
                var originalContact = (from c in _entities.ContactSet
                                       where c.Id == contactToEdit.Id
                                       select c).FirstOrDefault();
                _entities.ApplyPropertyChanges(originalContact.EntityKey.EntitySetName, contactToEdit);
                _entities.SaveChanges();
                return RedirectToAction("Index");
            }
            catch
            {
                return View();
            }
        }

        public ActionResult Delete(int id)
        {
            var contactToDelete = (from c in _entities.ContactSet
                                   where c.Id == id
                                   select c).FirstOrDefault();

            return View(contactToDelete);
        }

        [AcceptVerbs(HttpVerbs.Post)]
        public ActionResult Delete(Contact contactToDelete)
        {
            try
            {
                var originalContact = (from c in _entities.ContactSet
                                       where c.Id == contactToDelete.Id
                                       select c).FirstOrDefault();

                _entities.DeleteObject(originalContact);
                _entities.SaveChanges();
                return RedirectToAction("Index");
            }
            catch
            {
                return View();
            }
        }

    }
}
```

Summary

In this iteration, we added basic form validation to our Contact Manager application. Our validation logic prevents users from submitting a new contact or editing an existing contact without supplying values for the FirstName and LastName properties. Furthermore, users must supply valid phone numbers and email addresses.

In this iteration, we added the validation logic to our Contact Manager application in the easiest way possible.

However, mixing our validation logic into our controller logic will create problems for us in the long term. Our application will be more difficult to maintain and modify over time.

In the next iteration, we will refactor our validation logic and database access logic out of our controllers. We'll take advantage of several software design principles to enable us to create a more loosely coupled, and more maintainable, application.

> In this fourth iteration, we take advantage of several software design patterns to make it easier to maintain and modify the Contact Manager application. For example, we refactor our application to use the Repository pattern and the Dependency Injection pattern.

Building a Contact Management ASP.NET MVC Application (C#)

In this series of tutorials, we build an entire Contact Management application from start to finish. The Contact Manager application enables you to store contact information - names, phone numbers and email addresses - for a list of people.

We build the application over multiple iterations. With each iteration, we gradually improve the application. The goal of this multiple iteration approach is to enable you to understand the reason for each change.

- Iteration #1 - Create the application. In the first iteration, we create the Contact Manager in the simplest way possible. We add support for basic database operations: Create, Read, Update, and Delete (CRUD).
- Iteration #2 - Make the application look nice. In this iteration, we improve the appearance of the application by modifying the default ASP.NET MVC view master page and cascading style sheet.
- Iteration #3 - Add form validation. In the third iteration, we add basic form validation. We prevent people from submitting a form without completing required form fields. We also validate email addresses and phone numbers.
- Iteration #4 - Make the application loosely coupled. In this fourth iteration, we take advantage of several software design patterns to make it easier to maintain and modify the Contact Manager application. For example, we refactor our application to use the Repository pattern and the Dependency Injection pattern.
- Iteration #5 - Create unit tests. In the fifth iteration, we make our application easier to maintain and modify by adding unit tests. We mock our data model classes and build unit tests for our controllers and validation logic.
- Iteration #6 - Use test-driven development. In this sixth iteration, we add new functionality to our application by writing unit tests first and writing code against the unit tests. In this iteration, we add contact groups.
- Iteration #7 - Add Ajax functionality. In the seventh iteration, we improve the responsiveness and performance of our application by adding support for Ajax.

This Iteration

In this fourth iteration of the Contact Manager application, we refactor the application to make the application more loosely coupled. When an application is loosely coupled, you can modify the code in one part of the application without needing to modify the code in other parts of the application. Loosely coupled applications are more resilient to change.

Currently, all of the data access and validation logic used by the Contact Manager application is contained in the controller classes. This is a bad idea. Whenever you need to modify one part of your application, you risk introducing bugs into another part of your application. For example, if you modify your validation logic, you risk introducing new bugs into your data access or controller logic.

> **NOTE**
> (SRP), a class should never have more than one reason to change. Mixing controller, validation, and database logic is a massive violation of the Single Responsibility Principle.

There are several reasons that you might need to modify your application. You might need to add a new feature to your application, you might need to fix a bug in your application, or you might need to modify how a feature of your application is implemented. Applications are rarely static. They tend to grow and mutate over time.

Imagine, for example, that you decide to change how you implement your data access layer. Right now, the Contact Manager application uses the Microsoft Entity Framework to access the database. However, you might decide to migrate to a new or alternative data access technology such as ADO.NET Data Services or NHibernate. However, because the data access code is not isolated from the validation and controller code, there is no way to modify the data access code in your application without modifying other code that is not directly related to data access.

When an application is loosely coupled, on the other hand, you can make changes to one part of an application without touching other parts of an application. For example, you can switch data access technologies without modifying your validation or controller logic.

In this iteration, we take advantage of several software design patterns that enable us to refactor our Contact Manager application into a more loosely coupled application. When we are done, the Contact Manager won t do anything that it didn't do before. However, we'll be able to change the application more easily in the future.

> **NOTE**
> Refactoring is the process of rewriting an application in such a way that it does not lose any existing functionality.

Using the Repository Software Design Pattern

Our first change is to take advantage of a software design pattern called the Repository pattern. We'll use the Repository pattern to isolate our data access code from the rest of our application.

Implementing the Repository pattern requires us to complete the following two steps:

1. Create an interface
2. Create a concrete class that implements the interface

First, we need to create an interface that describes all of the data access methods that we need to perform. The IContactManagerRepository interface is contained in Listing 1. This interface describes five methods: CreateContact(), DeleteContact(), EditContact(), GetContact, and ListContacts().

Listing 1 - Models\IContactManagerRepository.cs

```
using System;
using System.Collections.Generic;

namespace ContactManager.Models
{
    public interface IContactRepository
    {
        Contact CreateContact(Contact contactToCreate);
        void DeleteContact(Contact contactToDelete);
        Contact EditContact(Contact contactToUpdate);
        Contact GetContact(int id);
        IEnumerable<Contact> ListContacts();

    }
}
```

Next, we need to create a concrete class that implements the IContactManagerRepository interface. Because we are using the Microsoft Entity Framework to access the database, we'll create a new class named EntityContactManagerRepository. This class is contained in Listing 2.

Listing 2 - Models\EntityContactManagerRepository.cs

```
using System.Collections.Generic;
using System.Linq;

namespace ContactManager.Models
{
    public class EntityContactManagerRepository : ContactManager.Models.IContactManagerRepository
    {
        private ContactManagerDBEntities _entities = new ContactManagerDBEntities();

        public Contact GetContact(int id)
        {
            return (from c in _entities.ContactSet
                    where c.Id == id
                    select c).FirstOrDefault();
        }

        public IEnumerable ListContacts()
        {
            return _entities.ContactSet.ToList();
        }

        public Contact CreateContact(Contact contactToCreate)
        {
            _entities.AddToContactSet(contactToCreate);
            _entities.SaveChanges();
            return contactToCreate;
        }

        public Contact EditContact(Contact contactToEdit)
        {
            var originalContact = GetContact(contactToEdit.Id);
            _entities.ApplyPropertyChanges(originalContact.EntityKey.EntitySetName, contactToEdit);
            _entities.SaveChanges();
            return contactToEdit;
        }

        public void DeleteContact(Contact contactToDelete)
        {
            var originalContact = GetContact(contactToDelete.Id);
            _entities.DeleteObject(originalContact);
            _entities.SaveChanges();
        }

    }
}
```

Notice that the EntityContactManagerRepository class implements the IContactManagerRepository interface. The class implements all five of the methods described by that interface.

You might wonder why we need to bother with an interface. Why do we need to create both an interface and a class that implements it?

With one exception, the remainder of our application will interact with the interface and not the concrete class. Instead of calling the methods exposed by the EntityContactManagerRepository class, we'll call the methods exposed by the IContactManagerRepository interface.

That way, we can implement the interface with a new class without needing to modify the remainder of our application. For example, at some future date, we might want to implement an DataServicesContactManagerRepository class that implements the IContactManagerRepository interface. The DataServicesContactManagerRepository class might use ADO.NET Data Services to access a database instead of the Microsoft Entity Framework.

If our application code is programmed against the IContactManagerRepository interface instead of the concrete

EntityContactManagerRepository class then we can switch concrete classes without modifying any of the rest of our code. For example, we can switch from the EntityContactManagerRepository class to the DataServicesContactManagerRepository class without modifying our data access or validation logic.

Programming against interfaces (abstractions) instead of concrete classes makes our application more resilient to change.

> **NOTE**
> You can quickly create an interface from a concrete class within Visual Studio by selecting the menu option Refactor, Extract Interface. For example, you can create the EntityContactManagerRepository class first and then use Extract Interface to generate the IContactManagerRepository interface automatically.

Using the Dependency Injection Software Design Pattern

Now that we have migrated our data access code to a separate Repository class, we need to modify our Contact controller to use this class. We will take advantage of a software design pattern called Dependency Injection to use the Repository class in our controller.

The modified Contact controller is contained in Listing 3.

Listing 3 - Controllers\ContactController.cs

```
using System.Text.RegularExpressions;
using System.Web.Mvc;
using ContactManager.Models;

namespace ContactManager.Controllers
{
    public class ContactController : Controller
    {
        private IContactManagerRepository _repository;

        public ContactController()
            : this(new EntityContactManagerRepository())
        {}

        public ContactController(IContactManagerRepository repository)
        {
            _repository = repository;
        }

        protected void ValidateContact(Contact contactToValidate)
        {
            if (contactToValidate.FirstName.Trim().Length == 0)
                ModelState.AddModelError("FirstName", "First name is required.");
            if (contactToValidate.LastName.Trim().Length == 0)
                ModelState.AddModelError("LastName", "Last name is required.");
            if (contactToValidate.Phone.Length > 0 && !Regex.IsMatch(contactToValidate.Phone, @"((\(\d{3}\)
?)|(\d{3}-))?\d{3}-\d{4}"))
                ModelState.AddModelError("Phone", "Invalid phone number.");
            if (contactToValidate.Email.Length > 0 && !Regex.IsMatch(contactToValidate.Email, @"^[\w-
\.]+@([\w-]+\.)+[\w-]{2,4}$"))
                ModelState.AddModelError("Email", "Invalid email address.");
        }

        public ActionResult Index()
        {
            return View(_repository.ListContacts());
        }

        public ActionResult Create()
        {
```

```
            return View();
        }

        [AcceptVerbs(HttpVerbs.Post)]
        public ActionResult Create([Bind(Exclude = "Id")] Contact contactToCreate)
        {
            // Validation logic
            ValidateContact(contactToCreate);
            if (!ModelState.IsValid)
                return View();

            // Database logic
            try
            {
                _repository.CreateContact(contactToCreate);
                return RedirectToAction("Index");
            }
            catch
            {
                return View();
            }
        }

        public ActionResult Edit(int id)
        {
            return View(_repository.GetContact(id));
        }

        [AcceptVerbs(HttpVerbs.Post)]
        public ActionResult Edit(Contact contactToEdit)
        {
            // Validation logic
            ValidateContact(contactToEdit);
            if (!ModelState.IsValid)
                return View();

            // Database logic
            try
            {
                _repository.EditContact(contactToEdit);
                return RedirectToAction("Index");
            }
            catch
            {
                return View();
            }
        }

        public ActionResult Delete(int id)
        {
            return View(_repository.GetContact(id));
        }

        [AcceptVerbs(HttpVerbs.Post)]
        public ActionResult Delete(Contact contactToDelete)
        {
            try
            {
                _repository.DeleteContact(contactToDelete);
                return RedirectToAction("Index");
            }
            catch
            {
                return View();
            }
        }

    }
}
```

```
}
```

Notice that the Contact controller in Listing 3 has two constructors. The first constructor passes a concrete instance of the IContactManagerRepository interface to the second constructor. The Contact controller class uses *Constructor Dependency Injection*.

The one and only place that the EntityContactManagerRepository class is used is in the first constructor. The remainder of the class uses the IContactManagerRepository interface instead of the concrete EntityContactManagerRepository class.

This makes it easy to switch implementations of the IContactManagerRepository class in the future. If you want to use the DataServicesContactRepository class instead of the EntityContactManagerRepository class, just modify the first constructor.

Constructor Dependency injection also makes the Contact controller class very testable. In your unit tests, you can instantiate the Contact controller by passing a mock implementation of the IContactManagerRepository class. This feature of Dependency Injection will be very important to us in the next iteration when we build unit tests for the Contact Manager application.

> **NOTE**
> If you want to completely decouple the Contact controller class from a particular implementation of the IContactManagerRepository interface then you can take advantage of a framework that supports Dependency Injection such as StructureMap or the Microsoft Entity Framework (MEF). By taking advantage of a Dependency Injection framework, you never need to refer to a concrete class in your code.

Creating a Service Layer

You might have noticed that our validation logic is still mixed up with our controller logic in the modified controller class in Listing 3. For the same reason that it is a good idea to isolate our data access logic, it is a good idea to isolate our validation logic.

To fix this problem, we can create a separate *service layer*. The service layer is a separate layer that we can insert between our controller and repository classes. The service layer contains our business logic including all of our validation logic.

The ContactManagerService is contained in Listing 4. It contains the validation logic from the Contact controller class.

Listing 4 - Models\ContactManagerService.cs

```
using System.Collections.Generic;
using System.Text.RegularExpressions;
using System.Web.Mvc;
using ContactManager.Models.Validation;

namespace ContactManager.Models
{
    public class ContactManagerService : IContactManagerService
    {
        private IValidationDictionary _validationDictionary;
        private IContactManagerRepository _repository;

        public ContactManagerService(IValidationDictionary validationDictionary)
            : this(validationDictionary, new EntityContactManagerRepository())
        {}

        public ContactManagerService(IValidationDictionary validationDictionary, IContactManagerRepository
repository)
        {
```

```
        {
            _validationDictionary = validationDictionary;
            _repository = repository;
        }

        public bool ValidateContact(Contact contactToValidate)
        {
            if (contactToValidate.FirstName.Trim().Length == 0)
                _validationDictionary.AddError("FirstName", "First name is required.");
            if (contactToValidate.LastName.Trim().Length == 0)
                _validationDictionary.AddError("LastName", "Last name is required.");
            if (contactToValidate.Phone.Length > 0 && !Regex.IsMatch(contactToValidate.Phone, @"((\(\d{3}\)
?)|(\d{3}-))?\d{3}-\d{4}"))
                _validationDictionary.AddError("Phone", "Invalid phone number.");
            if (contactToValidate.Email.Length > 0 && !Regex.IsMatch(contactToValidate.Email, @"^[\w-
\.]+@([\w-]+\.)+[\w-]{2,4}$"))
                _validationDictionary.AddError("Email", "Invalid email address.");
            return _validationDictionary.IsValid;
        }

        #region IContactManagerService Members

        public bool CreateContact(Contact contactToCreate)
        {
            // Validation logic
            if (!ValidateContact(contactToCreate))
                return false;

            // Database logic
            try
            {
                _repository.CreateContact(contactToCreate);
            }
            catch
            {
                return false;
            }
            return true;
        }

        public bool EditContact(Contact contactToEdit)
        {
            // Validation logic
            if (!ValidateContact(contactToEdit))
                return false;

            // Database logic
            try
            {
                _repository.EditContact(contactToEdit);
            }
            catch
            {
                return false;
            }
            return true;
        }

        public bool DeleteContact(Contact contactToDelete)
        {
            try
            {
                _repository.DeleteContact(contactToDelete);
            }
            catch
            {
                return false;
            }
            return true;
```

```
        }

        public Contact GetContact(int id)
        {
            return _repository.GetContact(id);
        }

        public IEnumerable<Contact> ListContacts()
        {
            return _repository.ListContacts();
        }

        #endregion
    }
}
```

Notice that the constructor for the ContactManagerService requires a ValidationDictionary. The service layer communicates with the controller layer through this ValidationDictionary. We discuss the ValidationDictionary in detail in the following section when we discuss the Decorator pattern.

Notice, furthermore, that the ContactManagerService implements the IContactManagerService interface. You should always strive to program against interfaces instead of concrete classes. Other classes in the Contact Manager application do not interact with the ContactManagerService class directly. Instead, with one exception, the remainder of the Contact Manager application is programmed against the IContactManagerService interface.

The IContactManagerService interface is contained in Listing 5.

Listing 5 - Models\IContactManagerService.cs

```
using System.Collections.Generic;

namespace ContactManager.Models
{
    public interface IContactManagerService
    {
        bool CreateContact(Contact contactToCreate);
        bool DeleteContact(Contact contactToDelete);
        bool EditContact(Contact contactToEdit);
        Contact GetContact(int id);
        IEnumerable ListContacts();
    }
}
```

The modified Contact controller class is contained in Listing 6. Notice that the Contact controller no longer interacts with the ContactManager repository. Instead, the Contact controller interacts with the ContactManager service. Each layer is isolated as much as possible from other layers.

Listing 6 - Controllers\ContactController.cs

```
using System.Web.Mvc;
using ContactManager.Models;

namespace ContactManager.Controllers
{
    public class ContactController : Controller
    {
        private IContactManagerService _service;

        public ContactController()
        {
            _service = new ContactManagerService(new ModelStateWrapper(this.ModelState));

        }

        public ContactController(IContactManagerService service)
        {
            _service = service;
        }

        public ActionResult Index()
        {
            return View(_service.ListContacts());
        }

        public ActionResult Create()
        {
            return View();
        }

        [AcceptVerbs(HttpVerbs.Post)]
        public ActionResult Create([Bind(Exclude = "Id")] Contact contactToCreate)
        {
            if (_service.CreateContact(contactToCreate))
                return RedirectToAction("Index");
            return View();
        }

        public ActionResult Edit(int id)
        {
            return View(_service.GetContact(id));
        }

        [AcceptVerbs(HttpVerbs.Post)]
        public ActionResult Edit(Contact contactToEdit)
        {
            if (_service.EditContact(contactToEdit))
                return RedirectToAction("Index");
            return View();
        }

        public ActionResult Delete(int id)
        {
            return View(_service.GetContact(id));
        }

        [AcceptVerbs(HttpVerbs.Post)]
        public ActionResult Delete(Contact contactToDelete)
        {
            if (_service.DeleteContact(contactToDelete))
                return RedirectToAction("Index");
            return View();
        }

    }
}
```

Our application no longer runs afoul of the Single Responsibility Principle (SRP). The Contact controller in Listing 6 has been stripped of every responsibility other than controlling the flow of application execution. All the validation logic has been removed from the Contact controller and pushed into the service layer. All of the database logic has been pushed into the repository layer.

Using the Decorator Pattern

We want to be able to completely decouple our service layer from our controller layer. In principle, we should be able to compile our service layer in a separate assembly from our controller layer without needing to add a reference to our MVC application.

However, our service layer needs to be able to pass validation error messages back to the controller layer. How can we enable the service layer to communicate validation error messages without coupling the controller and service layer? We can take advantage of a software design pattern named the Decorator pattern.

A controller uses a ModelStateDictionary named ModelState to represent validation errors. Therefore, you might be tempted to pass ModelState from the controller layer to the service layer. However, using ModelState in the service layer would make your service layer dependent on a feature of the ASP.NET MVC framework. This would be bad because, someday, you might want to use the service layer with a WPF application instead of an ASP.NET MVC application. In that case, you wouldn't want to reference the ASP.NET MVC framework to use the ModelStateDictionary class.

The Decorator pattern enables you to wrap an existing class in a new class in order to implement an interface. Our Contact Manager project includes the ModelStateWrapper class contained in Listing 7. The ModelStateWrapper class implements the interface in Listing 8.

Listing 7 - Models\Validation\ModelStateWrapper.cs

```
using System.Web.Mvc;

namespace ContactManager.Models.Validation
{
    public class ModelStateWrapper : IValidationDictionary
    {
        private ModelStateDictionary _modelState;

        public ModelStateWrapper(ModelStateDictionary modelState)
        {
            _modelState = modelState;
        }

        public void AddError(string key, string errorMessage)
        {
            _modelState.AddModelError(key, errorMessage);
        }

        public bool IsValid
        {
            get { return _modelState.IsValid; }
        }
    }
}
```

Listing 8 - Models\Validation\IValidationDictionary.cs

```
namespace ContactManager.Models.Validation
{
    public interface IValidationDictionary
    {
        void AddError(string key, string errorMessage);
        bool IsValid {get;}
    }
}
```

If you take a close look at Listing 5 then you'll see that the ContactManager service layer uses the IValidationDictionary interface exclusively. The ContactManager service is not dependent on the ModelStateDictionary class. When the Contact controller creates the ContactManager service, the controller wraps its ModelState like this:

```
_service = new ContactManagerService(new ModelStateWrapper(this.ModelState));
```

Summary

In this iteration, we did not add any new functionality to the Contact Manager application. The goal of this iteration was to refactor the Contact Manager application so that is easier to maintain and modify.

First, we implemented the Repository software design pattern. We migrated all of the data access code to a separate ContactManager repository class.

We also isolated our validation logic from our controller logic. We created a separate service layer that contains all of our validation code. The controller layer interacts with the service layer, and the service layer interacts with the repository layer.

When we created the service layer, we took advantage of the Decorator pattern to isolate ModelState from our service layer. In our service layer, we programmed against the IValidationDictionary interface instead of ModelState.

Finally, we took advantage of a software design pattern named the Dependency Injection pattern. This pattern enables us to program against interfaces (abstractions) instead of concrete classes. Implementing the Dependency Injection design pattern also makes our code more testable. In the next iteration, we add unit tests to our project.

Iteration #5 – Create unit tests (C#)

> In the fifth iteration, we make our application easier to maintain and modify by adding unit tests. We mock our data model classes and build unit tests for our controllers and validation logic.

Building a Contact Management ASP.NET MVC Application (C#)

In this series of tutorials, we build an entire Contact Management application from start to finish. The Contact Manager application enables you to store contact information - names, phone numbers and email addresses - for a list of people.

We build the application over multiple iterations. With each iteration, we gradually improve the application. The goal of this multiple iteration approach is to enable you to understand the reason for each change.

- Iteration #1 - Create the application. In the first iteration, we create the Contact Manager in the simplest way possible. We add support for basic database operations: Create, Read, Update, and Delete (CRUD).
- Iteration #2 - Make the application look nice. In this iteration, we improve the appearance of the application by modifying the default ASP.NET MVC view master page and cascading style sheet.
- Iteration #3 - Add form validation. In the third iteration, we add basic form validation. We prevent people from submitting a form without completing required form fields. We also validate email addresses and phone numbers.
- Iteration #4 - Make the application loosely coupled. In this fourth iteration, we take advantage of several software design patterns to make it easier to maintain and modify the Contact Manager application. For example, we refactor our application to use the Repository pattern and the Dependency Injection pattern.
- Iteration #5 - Create unit tests. In the fifth iteration, we make our application easier to maintain and modify by adding unit tests. We mock our data model classes and build unit tests for our controllers and validation logic.
- Iteration #6 - Use test-driven development. In this sixth iteration, we add new functionality to our application by writing unit tests first and writing code against the unit tests. In this iteration, we add contact groups.
- Iteration #7 - Add Ajax functionality. In the seventh iteration, we improve the responsiveness and performance of our application by adding support for Ajax.

This Iteration

In the previous iteration of the Contact Manager application, we refactored the application to be more loosely coupled. We separated the application into distinct controller, service, and repository layers. Each layer interacts with the layer beneath it through interfaces.

We refactored the application to make the application easier to maintain and modify. For example, if we need to use a new data access technology, we can simply change the repository layer without touching the controller or service layer. By making the Contact Manager loosely coupled, we ve made the application more resilient to

change.

But, what happens when we need to add a new feature to the Contact Manager application? Or, what happens when we fix a bug? A sad, but well proven, truth of writing code is that whenever you touch code you create the risk of introducing new bugs.

For example, one fine day, your manager might ask you to add a new feature to the Contact Manager. She wants you to add support for Contact Groups. She wants you to enable users to organize their contacts into groups such as Friends, Business, and so on.

In order to implement this new feature, you'll need to modify all three layers of the Contact Manager application. You'll need to add new functionality to the controllers, the service layer, and the repository. As soon as you start modifying code, you risk breaking functionality that worked before.

Refactoring our application into separate layers, as we did in the previous iteration, was a good thing. It was a good thing because it enables us to make changes to entire layers without touching the rest of the application. However, if you want to make the code within a layer easier to maintain and modify, you need to create unit tests for the code.

You use a unit test to test an individual unit of code. These units of code are smaller than entire application layers. Typically, you use a unit test to verify whether a particular method in your code behaves in the way that you expect. For example, you would create a unit test for the CreateContact() method exposed by the ContactManagerService class.

The unit tests for an application work just like a safety net. Whenever you modify code in an application, you can run a set of unit tests to check whether the modification breaks existing functionality. Unit tests make your code safe to modify. Unit tests make all of the code in your application more resilient to change.

In this iteration, we add unit tests to our Contact Manager application. That way, in the next iteration, we can add Contact Groups to our application without worrying about breaking existing functionality.

> **NOTE**
> There are a variety of unit testing frameworks including NUnit, xUnit.net, and MbUnit. In this tutorial, we use the unit testing framework included with Visual Studio. However, you could just as easily use one of these alternative frameworks.

What Gets Tested

In the perfect world, all of your code would be covered by unit tests. In the perfect world, you would have the perfect safety net. You would be able to modify any line of code in your application and know instantly, by executing your unit tests, whether the change broke existing functionality.

However, we don t live in a perfect world. In practice, when writing unit tests, you concentrate on writing tests for your business logic (for example, validation logic). In particular, you *do not* write unit tests for your data access logic or your view logic.

To be useful, unit tests must execute very quickly. You easily can accumulate hundreds (or even thousands) of unit tests for an application. If the unit tests take a long time to run then you'll avoid executing them. In other words, long running unit tests are useless for day to day coding purposes.

For this reason, you typically do not write unit tests for code that interacts with a database. Running hundreds of unit tests against a live database would be too slow. Instead, you mock your database and write code that interacts with the mock database (we discuss mocking a database below).

For a similar reason, you typically do not write unit tests for views. In order to test a view, you must spin up a web server. Because spinning up a web server is a relatively slow process, creating unit tests for your views is not recommended.

If your view contains complicated logic then you should consider moving the logic into Helper methods. You can write unit tests for Helper methods that execute without spinning up a web server.

> **NOTE**
> While writing tests for data access logic or view logic is not a good idea when writing unit tests, these tests can be very valuable when building functional or integration tests.

> **NOTE**
> ASP.NET MVC is the Web Forms View Engine. While the Web Forms View Engine is dependent on a web server, other view engines might not be.

Using a Mock Object Framework

When building unit tests, you almost always need to take advantage of a Mock Object framework. A Mock Object framework enables you to create mocks and stubs for the classes in your application.

For example, you can use a Mock Object framework to generate a mock version of your repository class. That way, you can use the mock repository class instead of the real repository class in your unit tests. Using the mock repository enables you to avoid executing database code when executing a unit test.

Visual Studio does not include a Mock Object framework. However, there are several commercial and open source Mock Object frameworks available for the .NET framework:

1. Moq - This framework is available under the open source BSD license. You can download Moq from https://code.google.com/p/moq/.
2. Rhino Mocks - This framework is available under the open source BSD license. You can download Rhino Mocks from http://ayende.com/projects/rhino-mocks.aspx.
3. Typemock Isolator - This is a commercial framework. You can download a trial version from http://www.typemock.com/.

In this tutorial, I decided to use Moq. However, you could just as easily use Rhino Mocks or Typemock Isolator to create the Mock objects for the Contact Manager application.

Before you can use Moq, you need to complete the following steps:

1. .
2. Before you unzip the download, make sure that you right-click the file and click the button labeled **Unblock** (see Figure 1).
3. Unzip the download.
4. Add a reference to the Moq assembly by right-clicking the References folder in the ContactManager.Tests project and selecting **Add Reference**. Under the Browse tab, browse to the folder where you unzipped Moq and select the Moq.dll assembly. Click the **OK** button.
5. After you complete these steps, your References folder should look like Figure 2.

Figure 01: Unblocking Moq(Click to view full-size image)

Figure 02: References after adding Moq(Click to view full-size image)

Creating Unit Tests for the Service Layer

Let s start by creating a set of unit tests for our Contact Manager application s service layer. We'll use these tests to verify our validation logic.

Create a new folder named Models in the ContactManager.Tests project. Next, right-click the Models folder and select **Add, New Test**. The **Add New Test** dialog shown in Figure 3 appears. Select the **Unit Test** template and name your new test ContactManagerServiceTest.cs. Click the **OK** button to add your new test to your Test Project.

> **NOTE**
>
> In general, you want the folder structure of your Test Project to match the folder structure of your ASP.NET MVC project. For example, you place controller tests in a Controllers folder, model tests in a Models folder, and so on.

Figure 03: Models\ContactManagerServiceTest.cs(Click to view full-size image)

Initially, we want to test the CreateContact() method exposed by the ContactManagerService class. We'll create the following five tests:

- CreateContact() - Tests that CreateContact() returns the value true when a valid Contact is passed to the method.
- CreateContactRequiredFirstName() - Tests that an error message is added to model state when a Contact with a missing first name is passed to the CreateContact() method.
- CreateContactRequiredLastName() - Tests that an error message is added to model state when a Contact with a missing last name is passed to the CreateContact() method.
- CreateContactInvalidPhone() - Tests that an error message is added to model state when a Contact with an invalid phone number is passed to the CreateContact() method.
- CreateContactInvalidEmail() - Tests that an error message is added to model state when a Contact with an invalid email address is passed to the CreateContact() method..

The first test verifies that a valid Contact does not generate a validation error. The remaining tests check each of the validation rules.

The code for these tests is contained in Listing 1.

Listing 1 - Models\ContactManagerServiceTest.cs

```
using System.Web.Mvc;
using ContactManager.Models;
using Microsoft.VisualStudio.TestTools.UnitTesting;
using Moq;

namespace ContactManager.Tests.Models
{
    [TestClass]
    public class ContactManagerServiceTest
    {
        private Mock<IContactManagerRepository> _mockRepository;
        private ModelStateDictionary _modelState;
        private IContactManagerService _service;

        [TestInitialize]
        public void Initialize()
        {
            _mockRepository = new Mock<IContactManagerRepository>();
            _modelState = new ModelStateDictionary();
            _service = new ContactManagerService(new ModelStateWrapper(_modelState), _mockRepository.Object);
        }

        [TestMethod]
        public void CreateContact()
        {
            // Arrange
            var contact = Contact.CreateContact(-1, "Stephen", "Walther", "555-5555", "steve@somewhere.com");

            // Act
            var result = _service.CreateContact(contact);

            // Assert
            Assert.IsTrue(result);
        }

        [TestMethod]
        public void CreateContactRequiredFirstName()
        {
            // Arrange
            var contact = Contact.CreateContact(-1, string.Empty, "Walther", "555-5555",
"steve@somewhere.com");
```

```
            // Act
            var result = _service.CreateContact(contact);

            // Assert
            Assert.IsFalse(result);
            var error = _modelState["FirstName"].Errors[0];
            Assert.AreEqual("First name is required.", error.ErrorMessage);
        }

        [TestMethod]
        public void CreateContactRequiredLastName()
        {
            // Arrange
            var contact = Contact.CreateContact(-1, "Stephen", string.Empty, "555-5555",
"steve@somewhere.com");

            // Act
            var result = _service.CreateContact(contact);

            // Assert
            Assert.IsFalse(result);
            var error = _modelState["LastName"].Errors[0];
            Assert.AreEqual("Last name is required.", error.ErrorMessage);
        }

        [TestMethod]
        public void CreateContactInvalidPhone()
        {
            // Arrange
            var contact = Contact.CreateContact(-1, "Stephen", "Walther", "apple", "steve@somewhere.com");

            // Act
            var result = _service.CreateContact(contact);

            // Assert
            Assert.IsFalse(result);
            var error = _modelState["Phone"].Errors[0];
            Assert.AreEqual("Invalid phone number.", error.ErrorMessage);
        }

        [TestMethod]
        public void CreateContactInvalidEmail()
        {
            // Arrange
            var contact = Contact.CreateContact(-1, "Stephen", "Walther", "555-5555", "apple");

            // Act
            var result = _service.CreateContact(contact);

            // Assert
            Assert.IsFalse(result);
            var error = _modelState["Email"].Errors[0];
            Assert.AreEqual("Invalid email address.", error.ErrorMessage);
        }
    }
}
```

Because we use the Contact class in Listing 1, we need to add a reference to the Microsoft Entity Framework to our Test project. Add a reference to the System.Data.Entity assembly.

Listing 1 contains a method named Initialize() that is decorated with the [TestInitialize] attribute. This method is called automatically before each of the unit tests is run (it is called 5 times right before each of the unit tests). The Initialize() method creates a mock repository with the following line of code:

```
_mockRepository = new Mock<IContactManagerRepository>();
```

This line of code uses the Moq framework to generate a mock repository from the IContactManagerRepository interface. The mock repository is used instead of the actual EntityContactManagerRepository to avoid accessing the database when each unit test is run. The mock repository implements the methods of the IContactManagerRepository interface, but the methods don t actually do anything.

> **NOTE**
>
> When using the Moq framework, there is a distinction between _mockRepository and _mockRepository.Object. The former refers to the Mock<IContactManagerRepository> class that contains methods for specifying how the mock repository will behave. The latter refers to the actual mock repository that implements the IContactManagerRepository interface.

The mock repository is used in the Initialize() method when creating an instance of the ContactManagerService class. All of the individual unit tests use this instance of the ContactManagerService class.

Listing 1 contains five methods that correspond to each of the unit tests. Each of these methods is decorated with the [TestMethod] attribute. When you run the unit tests, any method that has this attribute is called. In other words, any method that is decorated with the [TestMethod] attribute is a unit test.

The first unit test, named CreateContact(), verifies that calling CreateContact() returns the value true when a valid instance of the Contact class is passed to the method. The test creates an instance of the Contact class, calls the CreateContact() method, and verifies that CreateContact() returns the value true.

The remaining tests verify that when the CreateContact() method is called with an invalid Contact then the method returns false and the expected validation error message is added to model state. For example, the CreateContactRequiredFirstName() test creates an instance of the Contact class with an empty string for its FirstName property. Next, the CreateContact() method is called with the invalid Contact. Finally, the test verifies that CreateContact() returns false and that model state contains the expected validation error message "First name is required."

You can run the unit tests in Listing 1 by selecting the menu option **Test, Run, All Tests in Solution (CTRL+R, A)**. The results of the tests are displayed in the Test Results window (see Figure 4).

Figure 04: Test Results (Click to view full-size image)

Creating Unit Tests for Controllers

ASP.NETMVC application control the flow of user interaction. When testing a controller, you want to test whether the controller returns the right action result and view data. You also might want to test whether a controller interacts with model classes in the manner expected.

For example, Listing 2 contains two unit tests for the Contact controller Create() method. The first unit test verifies that when a valid Contact is passed to the Create() method then the Create() method redirects to the Index action. In other words, when passed a valid Contact, the Create() method should return a RedirectToRouteResult that represents the Index action.

We don t want to test the ContactManager service layer when we are testing the controller layer. Therefore, we mock the service layer with the following code in the Initialize method:

```
_service = new Mock();
```

In the CreateValidContact() unit test, we mock the behavior of calling the service layer CreateContact() method with the following line of code:

```
_service.Expect(s => s.CreateContact(contact)).Returns(true);
```

This line of code causes the mock ContactManager service to return the value true when its CreateContact() method is called. By mocking the service layer, we can test the behavior of our controller without needing to execute any code in the service layer.

The second unit test verifies that the Create() action returns the Create view when an invalid contact is passed to the method. We cause the service layer CreateContact() method to return the value false with the following line of code:

```
_service.Expect(s => s.CreateContact(contact)).Returns(false);
```

If the Create() method behaves as we expect then it should return the Create view when the service layer returns the value false. That way, the controller can display the validation error messages in the Create view and the user has a chance to correct that invalid Contact properties.

If you plan to build unit tests for your controllers then you need to return explicit view names from your controller actions. For example, do not return a view like this:

return View();

Instead, return the view like this:

return View("Create");

If you are not explicit when returning a view then the ViewResult.ViewName property returns an empty string.

Listing 2 - Controllers\ContactControllerTest.cs

```
using System.Web.Mvc;
using ContactManager.Controllers;
using ContactManager.Models;
using Microsoft.VisualStudio.TestTools.UnitTesting;
using Moq;

namespace ContactManager.Tests.Controllers
{
    [TestClass]
    public class ContactControllerTest
    {
        private Mock<IContactManagerService> _service;

        [TestInitialize]
        public void Initialize()
        {
            _service = new Mock<IContactManagerService>();
        }

        [TestMethod]
        public void CreateValidContact()
        {
            // Arrange
            var contact = new Contact();
            _service.Expect(s => s.CreateContact(contact)).Returns(true);
            var controller = new ContactController(_service.Object);

            // Act
            var result = (RedirectToRouteResult)controller.Create(contact);

            // Assert
            Assert.AreEqual("Index", result.RouteValues["action"]);
        }

        [TestMethod]
        public void CreateInvalidContact()
        {
            // Arrange
            var contact = new Contact();
            _service.Expect(s => s.CreateContact(contact)).Returns(false);
            var controller = new ContactController(_service.Object);

            // Act
            var result = (ViewResult)controller.Create(contact);

            // Assert
            Assert.AreEqual("Create", result.ViewName);
        }

    }
}
```

Summary

In this iteration, we created unit tests for our Contact Manager application. We can run these unit tests at any time to verify that our application still behaves in the manner that we expect. The unit tests act as a safety net for our application enabling us to safely modify our application in the future.

We created two sets of unit tests. First, we tested our validation logic by creating unit tests for our service layer. Next, we tested our flow control logic by creating unit tests for our controller layer. When testing our service layer, we isolated our tests for our service layer from our repository layer by mocking our repository layer. When testing the controller layer, we isolated our tests for our controller layer by mocking the service layer.

In the next iteration, we modify the Contact Manager application so that it supports Contact Groups. We'll add this

new functionality to our application using a software design process called test-driven development.

> In this sixth iteration, we add new functionality to our application by writing unit tests first and writing code against the unit tests. In this iteration, we add contact groups.

Building a Contact Management ASP.NET MVC Application (C#)

In this series of tutorials, we build an entire Contact Management application from start to finish. The Contact Manager application enables you to store contact information - names, phone numbers and email addresses - for a list of people.

We build the application over multiple iterations. With each iteration, we gradually improve the application. The goal of this multiple iteration approach is to enable you to understand the reason for each change.

- Iteration #1 - Create the application. In the first iteration, we create the Contact Manager in the simplest way possible. We add support for basic database operations: Create, Read, Update, and Delete (CRUD).
- Iteration #2 - Make the application look nice. In this iteration, we improve the appearance of the application by modifying the default ASP.NET MVC view master page and cascading style sheet.
- Iteration #3 - Add form validation. In the third iteration, we add basic form validation. We prevent people from submitting a form without completing required form fields. We also validate email addresses and phone numbers.
- Iteration #4 - Make the application loosely coupled. In this fourth iteration, we take advantage of several software design patterns to make it easier to maintain and modify the Contact Manager application. For example, we refactor our application to use the Repository pattern and the Dependency Injection pattern.
- Iteration #5 - Create unit tests. In the fifth iteration, we make our application easier to maintain and modify by adding unit tests. We mock our data model classes and build unit tests for our controllers and validation logic.
- Iteration #6 - Use test-driven development. In this sixth iteration, we add new functionality to our application by writing unit tests first and writing code against the unit tests. In this iteration, we add contact groups.
- Iteration #7 - Add Ajax functionality. In the seventh iteration, we improve the responsiveness and performance of our application by adding support for Ajax.

This Iteration

In the previous iteration of the Contact Manager application, we created unit tests to provide a safety net for our code. The motivation for creating the unit tests was to make our code more resilient to change. With unit tests in place, we can happily make any change to our code and immediately know whether we have broken existing functionality.

In this iteration, we use unit tests for an entirely different purpose. In this iteration, we use unit tests as part of an application design philosophy called *test-driven development*. When you practice test-driven development, you

write tests first and then write code against the tests.

More precisely, when practicing test-driven development, there are three steps that you complete when creating code (Red/ Green/Refactor):

1. Write a unit test that fails (Red)
2. Write code that passes the unit test (Green)
3. Refactor your code (Refactor)

First, you write the unit test. The unit test should express your intention for how you expect your code to behave. When you first create the unit test, the unit test should fail. The test should fail because you have not yet written any application code that satisfies the test.

Next, you write just enough code in order for the unit test to pass. The goal is to write the code in the laziest, sloppiest and fastest possible way. You should not waste time thinking about the architecture of your application. Instead, you should focus on writing the minimal amount of code necessary to satisfy the intention expressed by the unit test.

Finally, after you have written enough code, you can step back and consider the overall architecture of your application. In this step, you rewrite (refactor) your code by taking advantage of software design patterns -- such as the repository pattern -- so that your code is more maintainable. You can fearlessly rewrite your code in this step because your code is covered by unit tests.

There are many benefits that result from practicing test-driven development. First, test-driven development forces you to focus on code that actually needs to be written. Because you are constantly focused on just writing enough code to pass a particular test, you are prevented from wandering into the weeds and writing massive amounts of code that you will never use.

Second, a "test first" design methodology forces you to write code from the perspective of how your code will be used. In other words, when practicing test-driven development, you are constantly writing your tests from a user perspective. Therefore, test-driven development can result in cleaner and more understandable APIs.

Finally, test-driven development forces you to write unit tests as part of the normal process of writing an application. As a project deadline approaches, testing is typically the first thing that goes out the window. When practicing test-driven development, on the other hand, you are more likely to be virtuous about writing unit tests because test-driven development makes unit tests central to the process of building an application.

> **NOTE**
> To learn more about test-driven development, I recommend that you read Michael Feathers book **Working Effectively with Legacy Code**.

In this iteration, we add a new feature to our Contact Manager application. We add support for Contact Groups. You can use Contact Groups to organize your contacts into categories such as Business and Friend groups.

We'll add this new functionality to our application by following a process of test-driven development. We'll write our unit tests first and we'll write all of our code against these tests.

What Gets Tested

As we discussed in the previous iteration, you typically do not write unit tests for data access logic or view logic. You don t write unit tests for data access logic because accessing a database is a relatively slow operation. You don t write unit tests for view logic because accessing a view requires spinning up a web server which is a relatively slow operation. You shouldn't write a unit test unless the test can be executed over and over again very fast

Because test-driven development is driven by unit tests, we focus initially on writing controller and business logic.

We avoid touching the database or views. We won't modify the database or create our views until the very end of this tutorial. We start with what can be tested.

Creating User Stories

When practicing test-driven development, you always start by writing a test. This immediately raises the question: How do you decide what test to write first? To answer this question, you should write a set of **user stories**.

A user story is a very brief (usually one sentence) description of a software requirement. It should be a non-technical description of a requirement written from a user perspective.

Here s the set of user stories that describe the features required by the new Contact Group functionality:

1. User can view a list of contact groups.
2. User can create a new contact group.
3. User can delete an existing contact group.
4. User can select a contact group when creating a new contact.
5. User can select a contact group when editing an existing contact.
6. A list of contact groups is displayed in the Index view.
7. When a user clicks a contact group, a list of matching contacts is displayed.

Notice that this list of user stories is completely understandable by a customer. There is no mention of technical implementation details.

While in the process of building your application, the set of user stories can become more refined. You might break a user story into multiple stories (requirements). For example, you might decide that creating a new contact group should involve validation. Submitting a contact group without a name should return a validation error.

After you create a list of user stories, you are ready to write your first unit test. We'll start by creating a unit test for viewing the list of contact groups.

Listing Contact Groups

Our first user story is that a user should be able to view a list of contact groups. We need to express this story with a test.

Create a new unit test by right-clicking the Controllers folder in the ContactManager.Tests project, selecting **Add, New Test**, and selecting the **Unit Test** template (see Figure 1). Name the new unit test GroupControllerTest.cs and click the **OK** button.

Figure 01: Adding the GroupControllerTest unit test(Click to view full-size image)

Our first unit test is contained in Listing 1. This test verifies that the Index() method of the Group controller returns a set of Groups. The test verifies that a collection of Groups is returned in view data.

Listing 1 - Controllers\GroupControllerTest.cs

```
using System;
using System.Text;
using System.Collections.Generic;
using System.Linq;
using Microsoft.VisualStudio.TestTools.UnitTesting;
using System.Web.Mvc;
using ContactManager.Models;

namespace ContactManager.Tests.Controllers
{
    [TestClass]
    public class GroupControllerTest
    {

        [TestMethod]
        public void Index()
        {
            // Arrange
            var controller = new GroupController();

            // Act
            var result = (ViewResult)controller.Index();

            // Assert
            Assert.IsInstanceOfType(result.ViewData.Model, typeof(IEnumerable));
        }
    }
}
```

When you first type the code in Listing 1 in Visual Studio, you'll get a lot of red squiggly lines. We have not created the GroupController or Group classes.

At this point, we can t even build our application so we can t execute our first unit test. That s good. That counts as a failing test. Therefore, we now have permission to start writing application code. We need to write enough code to execute our test.

The Group controller class in Listing 2 contains the bare minimum of code required to pass the unit test. The Index() action returns a statically coded list of Groups (the Group class is defined in Listing 3).

Listing 2 - Controllers\GroupController.cs

```
using System.Collections.Generic;
using System.Web.Mvc;
using ContactManager.Models;

namespace ContactManager.Controllers
{
    public class GroupController : Controller
    {
        public ActionResult Index()
        {
            var groups = new List();
            return View(groups);
        }

    }
}
```

Listing 3 - Models\Group.cs

```
namespace ContactManager.Models
{
    public class Group
    {
    }
}
```

After we add the GroupController and Group classes to our project, our first unit test completes successfully (see Figure 2). We have done the minimum work required to pass the test. It is time to celebrate.

Figure 02: Success!(Click to view full-size image)

Creating Contact Groups

Now we can move on to the second user story. We need to be able to create new contact groups. We need to express this intention with a test.

The test in Listing 4 verifies that calling the Create() method with a new Group adds the Group to the list of Groups returned by the Index() method. In other words, if I create a new group then I should be able to get the new Group back from the list of Groups returned by the Index() method.

Listing 4 - Controllers\GroupControllerTest.cs

```
[TestMethod]
public void Create()
{
    // Arrange
    var controller = new GroupController();

    // Act
    var groupToCreate = new Group();
    controller.Create(groupToCreate);

    // Assert
    var result = (ViewResult)controller.Index();
    var groups = (IEnumerable<Group>)result.ViewData.Model;
    CollectionAssert.Contains(groups.ToList(), groupToCreate);
}
```

The test in Listing 4 calls the Group controller Create() method with a new contact Group. Next, the test verifies that calling the Group controller Index() method returns the new Group in view data.

The modified Group controller in Listing 5 contains the bare minimum of changes required to pass the new test.

Listing 5 - Controllers\GroupController.cs

```
using System.Collections.Generic;
using System.Web.Mvc;
using ContactManager.Models;
using System.Collections;

namespace ContactManager.Controllers
{
    public class GroupController : Controller
    {
        private IList<Group> _groups = new List<Group>();

        public ActionResult Index()
        {
            return View(_groups);
        }

        public ActionResult Create(Group groupToCreate)
        {
            _groups.Add(groupToCreate);
            return RedirectToAction("Index");
        }
    }
}
```

The Group controller in Listing 5 has a new Create() action. This action adds a Group to a collection of Groups. Notice that the Index() action has been modified to return the contents of the collection of Groups.

Once again, we have performed the bare minimum amount of work required to pass the unit test. After we make these changes to the Group controller, all of our unit tests pass.

Adding Validation

This requirement was not stated explicitly in the user story. However, it is reasonable to require that a Group have a name. Otherwise, organizing contacts into Groups would not be very useful.

Listing 6 contains a new test that expresses this intention. This test verifies that attempting to create a Group

without supplying a name results in a validation error message in model state.

Listing 6 - Controllers\GroupControllerTest.cs

```
[TestMethod]
public void CreateRequiredName()
{
    // Arrange
    var controller = new GroupController();

    // Act
    var groupToCreate = new Group();
    groupToCreate.Name = String.Empty;
    var result = (ViewResult)controller.Create(groupToCreate);

    // Assert
    var error = result.ViewData.ModelState["Name"].Errors[0];
    Assert.AreEqual("Name is required.", error.ErrorMessage);
}
```

In order to satisfy this test, we need to add a Name property to our Group class (see Listing 7). Furthermore, we need to add a tiny bit of validation logic to our Group controller s Create() action (see Listing 8).

Listing 7 - Models\Group.cs

```
namespace ContactManager.Models
{
    public class Group
    {
        public string Name { get; set; }
    }
}
```

Listing 8 - Controllers\GroupController.cs

```
public ActionResult Create(Group groupToCreate)
{
    // Validation logic
    if (groupToCreate.Name.Trim().Length == 0)
    {
        ModelState.AddModelError("Name", "Name is required.");
        return View("Create");
    }

    // Database logic
    _groups.Add(groupToCreate);
    return RedirectToAction("Index");
}
```

Notice that the Group controller Create() action now contains both validation and database logic. Currently, the database used by the Group controller consists of nothing more than an in-memory collection.

Time to Refactor

The third step in Red/Green/Refactor is the Refactor part. At this point, we need to step back from our code and consider how we can refactor our application to improve its design. The Refactor stage is the stage at which we think hard about the best way of implementing software design principles and patterns.

We are free to modify our code in any way that we choose to improve the design of the code. We have a safety net of unit tests that prevent us from breaking existing functionality.

Right now, our Group controller is a mess from the perspective of good software design. The Group controller contains a tangled mess of validation and data access code. To avoid violating the Single Responsibility Principle, we need to separate these concerns into different classes.

Our refactored Group controller class is contained in Listing 9. The controller has been modified to use the ContactManager service layer. This is the same service layer that we use with the Contact controller.

Listing 10 contains the new methods added to the ContactManager service layer to support validating, listing, and creating groups. The IContactManagerService interface was updated to include the new methods.

Listing 11 contains a new FakeContactManagerRepository class that implements the IContactManagerRepository interface. Unlike the EntityContactManagerRepository class that also implements the IContactManagerRepository interface, our new FakeContactManagerRepository class does not communicate with the database. The FakeContactManagerRepository class uses an in-memory collection as a proxy for the database. We'll use this class in our unit tests as a fake repository layer.

Listing 9 - Controllers\GroupController.cs

```
using System.Web.Mvc;
using ContactManager.Models;

namespace ContactManager.Controllers
{
    public class GroupController : Controller
    {

        private IContactManagerService _service;

        public GroupController()
        {
            _service = new ContactManagerService(new ModelStateWrapper(this.ModelState));
        }

        public GroupController(IContactManagerService service)
        {
            _service = service;
        }

        public ActionResult Index()
        {
            return View(_service.ListGroups());
        }

        public ActionResult Create(Group groupToCreate)
        {
            if (_service.CreateGroup(groupToCreate))
                return RedirectToAction("Index");
            return View("Create");
        }
    }
}
```

Listing 10 - Controllers\ContactManagerService.cs

```
public bool ValidateGroup(Group groupToValidate)
{
    if (groupToValidate.Name.Trim().Length == 0)
       _validationDictionary.AddError("Name", "Name is required.");
    return _validationDictionary.IsValid;
}

public bool CreateGroup(Group groupToCreate)
{
    // Validation logic
    if (!ValidateGroup(groupToCreate))
        return false;

    // Database logic
    try
    {
        _repository.CreateGroup(groupToCreate);
    }
    catch
    {
        return false;
    }
    return true;
}

public IEnumerable<Group> ListGroups()
{
    return _repository.ListGroups();
}
```

Listing 11 - Controllers\FakeContactManagerRepository.cs

```
using System;
using System.Collections.Generic;
using ContactManager.Models;

namespace ContactManager.Tests.Models
{
    public class FakeContactManagerRepository : IContactManagerRepository
    {
        private IList<Group> _groups = new List<Group>();

        #region IContactManagerRepository Members

        // Group methods

        public Group CreateGroup(Group groupToCreate)
        {
            _groups.Add(groupToCreate);
            return groupToCreate;
        }

        public IEnumerable<Group> ListGroups()
        {
            return _groups;
        }

        // Contact methods

        public Contact CreateContact(Contact contactToCreate)
        {
            throw new NotImplementedException();
        }

        public void DeleteContact(Contact contactToDelete)
        {
            throw new NotImplementedException();
        }

        public Contact EditContact(Contact contactToEdit)
        {
            throw new NotImplementedException();
        }

        public Contact GetContact(int id)
        {
            throw new NotImplementedException();
        }

        public IEnumerable<Contact> ListContacts()
        {
            throw new NotImplementedException();
        }

        #endregion
    }
}
```

Modifying the IContactManagerRepository interface requires use to implement the CreateGroup() and ListGroups() methods in the EntityContactManagerRepository class. The laziest and fastest way to do this is to add stub methods that look like this:

```
public Group CreateGroup(Group groupToCreate)
{
    throw new NotImplementedException();
}

public IEnumerable<Group> ListGroups()
{
    throw new NotImplementedException();
}
```

Finally, these changes to the design of our application require us to make some modifications to our unit tests. We now need to use the FakeContactManagerRepository when performing the unit tests. The updated GroupControllerTest class is contained in Listing 12.

Listing 12 - Controllers\GroupControllerTest.cs

```
using System.Collections.Generic;
using System.Web.Mvc;
using ContactManager.Controllers;
using ContactManager.Models;
using Microsoft.VisualStudio.TestTools.UnitTesting;
using System.Collections;
using System.Linq;
using System;
using ContactManager.Tests.Models;

namespace ContactManager.Tests.Controllers
{
    [TestClass]
    public class GroupControllerTest
    {
        private IContactManagerRepository _repository;
        private ModelStateDictionary _modelState;
        private IContactManagerService _service;

        [TestInitialize]
        public void Initialize()
        {
            _repository = new FakeContactManagerRepository();
            _modelState = new ModelStateDictionary();
            _service = new ContactManagerService(new ModelStateWrapper(_modelState), _repository);

        }

        [TestMethod]
        public void Index()
        {
            // Arrange
            var controller = new GroupController(_service);

            // Act
            var result = (ViewResult)controller.Index();

            // Assert
            Assert.IsInstanceOfType(result.ViewData.Model, typeof(IEnumerable));
        }

        [TestMethod]
        public void Create()
        {
            // Arrange
            var controller = new GroupController(_service);

            // Act
            var groupToCreate = new Group();
```

```
            groupToCreate.Name = "Business";
            controller.Create(groupToCreate);

            // Assert
            var result = (ViewResult)controller.Index();
            var groups = (IEnumerable)result.ViewData.Model;
            CollectionAssert.Contains(groups.ToList(), groupToCreate);
        }

        [TestMethod]
        public void CreateRequiredName()
        {
            // Arrange
            var controller = new GroupController(_service);

            // Act
            var groupToCreate = new Group();
            groupToCreate.Name = String.Empty;
            var result = (ViewResult)controller.Create(groupToCreate);

            // Assert
            var error = _modelState["Name"].Errors[0];
            Assert.AreEqual("Name is required.", error.ErrorMessage);
        }

    }
}
```

After we make all of these changes, once again, all of our unit tests pass. We have completed the entire cycle of Red/Green/Refactor. We have implemented the first two user stories. We now have supporting unit tests for the requirements expressed in the user stories. Implementing the remainder of the user stories involves repeating the same cycle of Red/Green/Refactor.

Modifying our Database

Unfortunately, even though we have satisfied all of the requirements expressed by our unit tests, our work is not done. We still need to modify our database.

We need to create a new Group database table. Follow these steps:

1. In the Server Explorer window, right-click the Tables folder and select the menu option **Add New Table**.
2. Enter the two columns described below in the Table Designer.
3. Mark the Id column as a primary key and Identity column.
4. Save the new table with the name Groups by clicking the icon of the floppy.

COLUMN NAME	DATA TYPE	ALLOW NULLS
Id	int	False
Name	nvarchar(50)	False

Next, we need to delete all of the data from the Contacts table (otherwise, we won't be able to create a relationship between the Contacts and Groups tables). Follow these steps:

1. Right-click the Contacts table and select the menu option **Show Table Data**.
2. Delete all of the rows.

Next, we need to define a relationship between the Groups database table and the existing Contacts database table. Follow these steps:

1. Double-click the Contacts table in the Server Explorer window to open the Table Designer.
2. Add a new integer column to the Contacts table named GroupId.
3. Click the Relationship button to open the Foreign Key Relationships dialog (see Figure 3).
4. Click the Add button.
5. Click the ellipsis button that appears next to the Table and Columns Specification button.
6. In the Tables and Columns dialog, select Groups as the primary key table and Id as the primary key column. Select Contacts as the foreign key table and GroupId as the foreign key column (see Figure 4). Click the OK button.
7. Under **INSERT and UPDATE Specification**, select the value **Cascade** for **Delete Rule**.
8. Click the Close button to close the Foreign Key Relationships dialog.
9. Click the Save button to save the changes to the Contacts table.

Figure 03: Creating a database table relationship (Click to view full-size image)

Figure 04: Specifying table relationships(Click to view full-size image)

Updating our Data Model

Next, we need to update our data model to represent the new database table. Follow these steps:

1. Double-click the ContactManagerModel.edmx file in the Models folder to open the Entity Designer.
2. Right-click the Designer surface and select the menu option **Update Model from Database**.
3. In the Update Wizard, select the Groups table and click the Finish button (see Figure 5).
4. Right-click the Groups entity and select the menu option **Rename**. Change the name of the *Groups* entity to *Group* (singular).
5. Right-click the Groups navigation property that appears at the bottom of the Contact entity. Change the name of the *Groups* navigation property to *Group* (singular).

Figure 05: Updating an Entity Framework model from the database(Click to view full-size image)

After you complete these steps, your data model will represent both the Contacts and Groups tables. The Entity Designer should show both entities (see Figure 6).

Figure 06: Entity Designer displaying Group and Contact(Click to view full-size image)

Creating our Repository Classes

Next, we need to implement our repository class. Over the course of this iteration, we added several new methods to the IContactManagerRepository interface while writing code to satisfy our unit tests. The final version of the IContactManagerRepository interface is contained in Listing 14.

Listing 14 - Models\IContactManagerRepository.cs

```
using System.Collections.Generic;

namespace ContactManager.Models
{
    public interface IContactManagerRepository
    {
        // Contact methods
        Contact CreateContact(int groupId, Contact contactToCreate);
        void DeleteContact(Contact contactToDelete);
        Contact EditContact(int groupId, Contact contactToEdit);
        Contact GetContact(int id);

        // Group methods
        Group CreateGroup(Group groupToCreate);
        IEnumerable<Group> ListGroups();
        Group GetGroup(int groupId);
        Group GetFirstGroup();
        void DeleteGroup(Group groupToDelete);
    }
}
```

We haven't actually implemented any of the methods related to working with contact groups. Currently, the EntityContactManagerRepository class has stub methods for each of the contact group methods listed in the IContactManagerRepository interface. For example, the ListGroups() method currently looks like this:

```
public IEnumerable<Group> ListGroups()
{
    throw new NotImplementedException();
}
```

The stub methods enabled us to compile our application and pass the unit tests. However, now it is time to actually implement these methods. The final version of the EntityContactManagerRepository class is contained in Listing 13.

Listing 13 - Models\EntityContactManagerRepository.cs

```
using System.Collections.Generic;
using System.Linq;
using System;

namespace ContactManager.Models
{
    public class EntityContactManagerRepository : ContactManager.Models.IContactManagerRepository
    {
        private ContactManagerDBEntities _entities = new ContactManagerDBEntities();

        // Contact methods

        public Contact GetContact(int id)
        {
            return (from c in _entities.ContactSet.Include("Group")
                    where c.Id == id
                    select c).FirstOrDefault();
        }

        public Contact CreateContact(int groupId, Contact contactToCreate)
        {
            // Associate group with contact
            contactToCreate.Group = GetGroup(groupId);

            // Save new contact
            _entities.AddToContactSet(contactToCreate);
            _entities.SaveChanges();
```

```
            return contactToCreate;
        }

        public Contact EditContact(int groupId, Contact contactToEdit)
        {
            // Get original contact
            var originalContact = GetContact(contactToEdit.Id);

            // Update with new group
            originalContact.Group = GetGroup(groupId);

            // Save changes
            _entities.ApplyPropertyChanges(originalContact.EntityKey.EntitySetName, contactToEdit);
            _entities.SaveChanges();
            return contactToEdit;
        }

        public void DeleteContact(Contact contactToDelete)
        {
            var originalContact = GetContact(contactToDelete.Id);
            _entities.DeleteObject(originalContact);
            _entities.SaveChanges();
        }

        public Group CreateGroup(Group groupToCreate)
        {
            _entities.AddToGroupSet(groupToCreate);
            _entities.SaveChanges();
            return groupToCreate;
        }

        // Group Methods

        public IEnumerable<Group> ListGroups()
        {
            return _entities.GroupSet.ToList();
        }

        public Group GetFirstGroup()
        {
            return _entities.GroupSet.Include("Contacts").FirstOrDefault();
        }

        public Group GetGroup(int id)
        {
            return (from g in _entities.GroupSet.Include("Contacts")
                        where g.Id == id
                        select g).FirstOrDefault();
        }

        public void DeleteGroup(Group groupToDelete)
        {
            var originalGroup = GetGroup(groupToDelete.Id);
            _entities.DeleteObject(originalGroup);
            _entities.SaveChanges();

        }

    }
}
```

Creating the Views

ASP.NET MVC application when you use the default ASP.NET view engine. So, you don t create views in response to a particular unit test. However, because an application would be useless without views, we can t complete this iteration without creating and modifying the views contained in the Contact Manager application.

We need to create the following new views for managing contact groups (see Figure 7):

- Views\Group\Index.aspx - Displays list of contact groups
- Views\Group\Delete.aspx - Displays confirmation form for deleting a contact group

Figure 07: The Group Index view(Click to view full-size image)

We need to modify the following existing views so that they include contact groups:

- Views\Home\Create.aspx
- Views\Home\Edit.aspx
- Views\Home\Index.aspx

You can see the modified views by looking at the Visual Studio application that accompanies this tutorial. For example, Figure 8 illustrates the Contact Index view.

Figure 08: The Contact Index view(Click to view full-size image)

Summary

In this iteration, we added new functionality to our Contact Manager application by following a test-driven development application design methodology. We started by creating a set of user stories. We created a set of unit

tests that corresponds to the requirements expressed by the user stories. Finally, we wrote just enough code to satisfy the requirements expressed by the unit tests.

After we finished writing enough code to satisfy the requirements expressed by the unit tests, we updated our database and views. We added a new Groups table to our database and updated our Entity Framework Data Model. We also created and modified a set of views.

In the next iteration -- the final iteration -- we rewrite our application to take advantage of Ajax. By taking advantage of Ajax, we'll improve the responsiveness and performance of the Contact Manager application.

Iteration #7 – Add Ajax functionality (C#)

> In the seventh iteration, we improve the responsiveness and performance of our application by adding support for Ajax.

Building a Contact Management ASP.NET MVC Application (C#)

In this series of tutorials, we build an entire Contact Management application from start to finish. The Contact Manager application enables you to store contact information - names, phone numbers and email addresses - for a list of people.

We build the application over multiple iterations. With each iteration, we gradually improve the application. The goal of this multiple iteration approach is to enable you to understand the reason for each change.

- Iteration #1 - Create the application. In the first iteration, we create the Contact Manager in the simplest way possible. We add support for basic database operations: Create, Read, Update, and Delete (CRUD).
- Iteration #2 - Make the application look nice. In this iteration, we improve the appearance of the application by modifying the default ASP.NET MVC view master page and cascading style sheet.
- Iteration #3 - Add form validation. In the third iteration, we add basic form validation. We prevent people from submitting a form without completing required form fields. We also validate email addresses and phone numbers.
- Iteration #4 - Make the application loosely coupled. In this fourth iteration, we take advantage of several software design patterns to make it easier to maintain and modify the Contact Manager application. For example, we refactor our application to use the Repository pattern and the Dependency Injection pattern.
- Iteration #5 - Create unit tests. In the fifth iteration, we make our application easier to maintain and modify by adding unit tests. We mock our data model classes and build unit tests for our controllers and validation logic.
- Iteration #6 - Use test-driven development. In this sixth iteration, we add new functionality to our application by writing unit tests first and writing code against the unit tests. In this iteration, we add contact groups.
- Iteration #7 - Add Ajax functionality. In the seventh iteration, we improve the responsiveness and performance of our application by adding support for Ajax.

This Iteration

In this iteration of the Contact Manager application, we refactor our application to make use of Ajax. By taking advantage of Ajax, we make our application more responsive. We can avoid rendering an entire page when we need to update only a certain region in a page.

We'll refactor our Index view so that we don t need to redisplay the entire page whenever someone selects a new contact group. Instead, when someone clicks a contact group, we'll just update the list of contacts and leave the rest of the page alone.

We'll also change the way our delete link works. Instead of displaying a separate confirmation page, we'll display a JavaScript confirmation dialog. If you confirm that you want to delete a contact, an HTTP DELETE operation is performed against the server to delete the contact record from the database.

Furthermore, we will take advantage of jQuery to add animation effects to our Index view. We'll display an animation when the new list of contacts is being fetched from the server.

Finally, we'll take advantage of the ASP.NET AJAX framework support for managing browser history. We'll create history points whenever we perform an Ajax call to update the contact list. That way, the browser backward and forward buttons will work.

Why use Ajax?

Using Ajax has many benefits. First, adding Ajax functionality to an application results in a better user experience. In a normal web application, the entire page must be posted back to the server each and every time a user performs an action. Whenever you perform an action, the browser locks and the user must wait until the entire page is fetched and redisplayed.

This would be an unacceptable experience in the case of a desktop application. But, traditionally, we lived with this bad user experience in the case of a web application because we did not know that we could do any better. We thought it was a limitation of web applications when, in actuality, it was just a limitation of our imaginations.

In an Ajax application, you don t need to bring the user experience to a halt just to update a page. Instead, you can perform an asynchronous request in the background to update the page. You don t force the user to wait while part of the page gets updated.

By taking advantage of Ajax, you also can improve the performance of your application. Consider how the Contact Manager application works right now without Ajax functionality. When you click a contact group, the entire Index view must be redisplayed. The list of contacts and list of contact groups must be retrieved from the database server. All of this data must be passed across the wire from web server to web browser.

After we add Ajax functionality to our application, however, we can avoid redisplaying the entire page when a user clicks a contact group. We no longer need to grab the contact groups from the database. We also don t need to push the entire Index view across the wire. By taking advantage of Ajax, we reduce the amount of work that our database server must perform and we reduce the amount of network traffic required by our application.

Don t be Afraid of Ajax

Some developers avoid using Ajax because they worry about downlevel browsers. They want to make sure that their web applications will still work when accessed by a browser that does not support JavaScript. Because Ajax depends on JavaScript, some developers avoid using Ajax.

However, if you are careful about how you implement Ajax then you can build applications that work with both uplevel and downlevel browsers. Our Contact Manager application will work with browsers that support JavaScript and browsers that do not.

If you use the Contact Manager application with a browser that supports JavaScript then you will have a better user experience. For example, when you click a contact group, only the region of the page that displays contacts will be updated.

If, on the other hand, you use the Contact Manager application with a browser that does not support JavaScript (or that has JavaScript disabled) then you will have a slightly less desirable user experience. For example, when you click a contact group, the entire Index view must be posted back to the browser in order to display the matching list of contacts.

Adding the Required JavaScript Files

We'll need to use three JavaScript files to add Ajax functionality to our application. All three of these files are included in the Scripts folder of a new ASP.NET MVC application.

If you plan to use Ajax in multiple pages in your application then it makes sense to include the required JavaScript files in your application s view master page. That way, the JavaScript files will be included in all of the pages in your application automatically.

Add the following JavaScript includes inside the <head> tag of your view master page:

```
<script src="../../Scripts/MicrosoftAjax.js" type="text/javascript"></script>
    <script src="../../Scripts/MicrosoftMvcAjax.js" type="text/javascript"></script>
    <script src="../../Scripts/jquery-1.2.6.min.js" type="text/javascript"></script>
```

Refactoring the Index View to use Ajax

Let s start by modifying our Index view so that clicking a contact group only updates the region of the view that displays contacts. The red box in Figure 1 contains the region that we want to update.

Figure 01: Updating only contacts(Click to view full-size image)

The first step is to separate the part of the view that we want to update asynchronously into a separate partial (view user control). The section of the Index view that displays the table of contacts has been moved into the partial in Listing 1.

Listing 1 - Views\Contact\ContactList.ascx

```
<%@ Control Language="C#" Inherits="System.Web.Mvc.ViewUserControl<ContactManager.Models.Group>" %>
<%@ Import Namespace="Helpers" %>
<table class="data-table" cellpadding="0" cellspacing="0">
    <thead>
        <tr>
            <th class="actions edit">
                Edit
            </th>
            <th class="actions delete">
                Delete
            </th>
            <th>
                Name
            </th>
            <th>
                Phone
            </th>
            <th>
                Email
            </th>
        </tr>
    </thead>
    <tbody>
        <% foreach (var item in Model.Contacts)
           { %>
        <tr>
            <td class="actions edit">
                <a href='<%= Url.Action("Edit", new {id=item.Id}) %>'><img src="../../Content/Edit.png"
alt="Edit" /></a>
            </td>
            <td class="actions delete">
                <a href='<%= Url.Action("Delete", new {id=item.Id}) %>'><img src="../../Content/Delete.png"
alt="Edit" /></a>
            </td>
            <th>
                <%= Html.Encode(item.FirstName) %>
                <%= Html.Encode(item.LastName) %>
            </th>
            <td>
                <%= Html.Encode(item.Phone) %>
            </td>
            <td>
                <%= Html.Encode(item.Email) %>
            </td>
        </tr>
        <% } %>
    </tbody>
</table>
```

Notice that the partial in Listing 1 has a different model than the Index view. The *Inherits* attribute in the <%@ Page %> directive specifies that the partial inherits from the ViewUserControl<Group> class.

The updated Index view is contained in Listing 2.

Listing 2 - Views\Contact\Index.aspx

```
<%@ Page Title="" Language="C#" MasterPageFile="~/Views/Shared/Site.Master"
Inherits="System.Web.Mvc.ViewPage<ContactManager.Models.ViewData.IndexModel>" %>
<%@ Import Namespace="Helpers" %>
<asp:Content ID="Content1" ContentPlaceHolderID="head" runat="server">
<title>Index</title>
</asp:Content>

<asp:Content ID="Content2" ContentPlaceHolderID="MainContent" runat="server">

<ul id="leftColumn">
<% foreach (var item in Model.Groups) { %>
    <li <%= Html.Selected(item.Id, Model.SelectedGroup.Id) %>>
    <%= Ajax.ActionLink(item.Name, "Index", new { id = item.Id }, new AjaxOptions { UpdateTargetId =
"divContactList"})%>
    </li>
<% } %>
</ul>
<div id="divContactList">
    <% Html.RenderPartial("ContactList", Model.SelectedGroup); %>
</div>

<div class="divContactList-bottom"> </div>
</asp:Content>
```

There are two things that you should notice about the updated view in Listing 2. First, notice that all of the content moved into the partial is replaced with a call to Html.RenderPartial(). The Html.RenderPartial() method is called when the Index view is first requested in order to display the initial set of contacts.

Second, notice that the Html.ActionLink() used to display contact groups has been replaced with an Ajax.ActionLink(). The Ajax.ActionLink() is called with the following parameters:

```
<%= Ajax.ActionLink(item.Name, "Index", new { id = item.Id }, new AjaxOptions { UpdateTargetId =
"divContactList"})%>
```

The first parameter represents the text to display for the link, the second parameter represents the route values, and the third parameter represents the Ajax options. In this case, we use the UpdateTargetId Ajax option to point to the HTML tag that we want to update after the Ajax request completes. We want to update the tag with the new list of contacts.

The updated Index() method of the Contact controller is contained in Listing 3.

Listing 3 - Controllers\ContactController.cs (Index method)

```
public ActionResult Index(int? id)
{
    // Get selected group
    var selectedGroup = _service.GetGroup(id);
    if (selectedGroup == null)
        return RedirectToAction("Index", "Group");

    // Normal Request
    if (!Request.IsAjaxRequest())
    {
        var model = new IndexModel
        {
            Groups = _service.ListGroups(),
            SelectedGroup = selectedGroup
        };
        return View("Index", model);
    }

    // Ajax Request
    return PartialView("ContactList", selectedGroup);
}
```

The updated Index() action conditionally returns one of two things. If the Index() action is invoked by an Ajax request then the controller returns a partial. Otherwise, the Index() action returns an entire view.

Notice that the Index() action does not need to return as much data when invoked by an Ajax request. In the context of a normal request, the Index action returns a list of all of the contact groups and the selected contact group. In the context of an Ajax request, the Index() action returns only the selected group. Ajax means less work on your database server.

Our modified Index view works in the case of both uplevel and downlevel browsers. If you click a contact group, and your browser supports JavaScript, then only the region of the view that contains the list of contacts is updated. If, on the other hand, your browser does not support JavaScript, then the entire view is updated.

Our updated Index view has one problem. When you click a contact group, the selected group is not highlighted. Because the list of groups is displayed outside of the region that is updated during an Ajax request, the right group does not get highlighted. We'll fix this issue in the next section.

Adding jQuery Animation Effects

Normally, when you click a link in a web page, you can use the browser progress bar to detect whether or not the browser is actively fetching the updated content. When performing an Ajax request, on the other hand, the browser progress bar does not show any progress. This can make users nervous. How do you know whether the browser has frozen?

There are several ways that you can indicate to a user that work is being performed while performing an Ajax request. One approach is to display a simple animation. For example, you can fade out a region when an Ajax request begins and fade in the region when the request completes.

We'll use the jQuery library which is included with the Microsoft ASP.NET MVC framework, to create the animation effects. The updated Index view is contained in Listing 4.

Listing 4 - Views\Contact\Index.aspx

```
<%@ Page Title="" Language="C#" MasterPageFile="~/Views/Shared/Site.Master"
Inherits="System.Web.Mvc.ViewPage<ContactManager.Models.ViewData.IndexModel>" %>
<%@ Import Namespace="Helpers" %>
<asp:Content ID="Content1" ContentPlaceHolderID="head" runat="server">
<title>Index</title>
</asp:Content>

<asp:Content ID="Content2" ContentPlaceHolderID="MainContent" runat="server">

<script type="text/javascript">

    function beginContactList(args) {
        // Highlight selected group
        $('#leftColumn li').removeClass('selected');
        $(this).parent().addClass('selected');

        // Animate
        $('#divContactList').fadeOut('normal');
    }

    function successContactList() {
        // Animate
        $('#divContactList').fadeIn('normal');
    }

    function failureContactList() {
        alert("Could not retrieve contacts.");
    }

</script>

<ul id="leftColumn">
<% foreach (var item in Model.Groups) { %>
    <li <%= Html.Selected(item.Id, Model.SelectedGroup.Id) %>>
    <%= Ajax.ActionLink(item.Name, "Index", new { id = item.Id }, new AjaxOptions { UpdateTargetId =
"divContactList", OnBegin = "beginContactList", OnSuccess = "successContactList", OnFailure =
"failureContactList" })%>
    </li>
<% } %>
</ul>
<div id="divContactList">
    <% Html.RenderPartial("ContactList", Model.SelectedGroup); %>
</div>

<div class="divContactList-bottom"> </div>
</asp:Content>
```

Notice that the updated Index view contains three new JavaScript functions. The first two functions use jQuery to fade out and fade in the list of contacts when you click a new contact group. The third function displays an error message when an Ajax request results in an error (for example, network timeout).

The first function also takes care of highlighting the selected group. A class= selected attribute is added to the parent element (the LI element) of the element clicked. Again, jQuery makes it easy to select the right element and add the CSS class.

These scripts are tied to the group links with the help of the Ajax.ActionLink() AjaxOptions parameter. The updated Ajax.ActionLink() method call looks like this:

```
<%= Ajax.ActionLink(item.Name, "Index", new { id = item.Id }, new AjaxOptions { UpdateTargetId =
"divContactList", OnBegin = "beginContactList", OnSuccess = "successContactList", OnFailure =
"failureContactList" })%>
```

Adding Browser History Support

Normally, when you click a link to update a page, your browser history is updated. That way, you can click the browser Back button to move back in time to the previous state of the page. For example, if you click the Friends contact group and then click the Business contact group, you can click the browser Back button to navigate back to the state of the page when the Friends contact group was selected.

Unfortunately, performing an Ajax request does not update browser history automatically. If you click a contact group, and the list of matching contacts is retrieved with an Ajax request, then the browser history is not updated. You cannot use the browser Back button to navigate back to a contact group after selecting a new contact group.

If you want users to be able to use the browser Back button after performing Ajax requests then you need to perform a little more work. You need to take advantage of the browser history management functionality built in the ASP.NET AJAX Framework.

ASP.NET AJAX browser history, you need to do three things:

1. Enable Browser History by setting the enableBrowserHistory property to true.
2. Save history points when the state of a view changes by calling the addHistoryPoint() method.
3. Reconstruct the state of the view when the navigate event is raised.

The updated Index view is contained in Listing 5.

Listing 5 - Views\Contact\Index.aspx

```
<%@ Page Title="" Language="C#" MasterPageFile="~/Views/Shared/Site.Master"
Inherits="System.Web.Mvc.ViewPage<ContactManager.Models.ViewData.IndexModel>" %>
<%@ Import Namespace="Helpers" %>
<asp:Content ID="Content1" ContentPlaceHolderID="head" runat="server">
<title>Index</title>
</asp:Content>

<asp:Content ID="Content2" ContentPlaceHolderID="MainContent" runat="server">

<script type="text/javascript">

    var _currentGroupId = -1;

    Sys.Application.add_init(pageInit);

    function pageInit() {
        // Enable history
        Sys.Application.set_enableHistory(true);

        // Add Handler for history
        Sys.Application.add_navigate(navigate);
    }

    function navigate(sender, e) {
        // Get groupId from address bar
        var groupId = e.get_state().groupId;

        // If groupId != currentGroupId then navigate
        if (groupId != _currentGroupId) {
            _currentGroupId = groupId;
            $("#divContactList").load("/Contact/Index/" + groupId);
            selectGroup(groupId);
        }
    }

    function selectGroup(groupId) {
        $('#leftColumn li').removeClass('selected');
        if (groupId)
            $('a[groupid=' + groupId + ']').parent().addClass('selected');
```

```
        else
            $('#leftColumn li:first').addClass('selected');
    }

    function beginContactList(args) {
        // Highlight selected group
        _currentGroupId = this.getAttribute("groupid");
        selectGroup(_currentGroupId);

        // Add history point
        Sys.Application.addHistoryPoint({ "groupId": _currentGroupId });

        // Animate
        $('#divContactList').fadeOut('normal');
    }

    function successContactList() {
        // Animate
        $('#divContactList').fadeIn('normal');
    }

    function failureContactList() {
        alert("Could not retrieve contacts.");
    }

</script>

<ul id="leftColumn">
<% foreach (var item in Model.Groups) { %>
    <li <%= Html.Selected(item.Id, Model.SelectedGroup.Id) %>>
    <%= Ajax.ActionLink(item.Name, "Index", new { id = item.Id }, new AjaxOptions { UpdateTargetId =
"divContactList", OnBegin = "beginContactList", OnSuccess = "successContactList", OnFailure =
"failureContactList" }, new { groupid = item.Id })%>
    </li>
<% } %>
</ul>
<div id="divContactList">
    <% Html.RenderPartial("ContactList", Model.SelectedGroup); %>
</div>

<div class="divContactList-bottom"> </div>
</asp:Content>
```

In Listing 5, Browser History is enabled in the pageInit() function. The pageInit() function is also used to set up the event handler for the navigate event. The navigate event is raised whenever the browser Forward or Back button causes the state of the page to change.

The beginContactList() method is called when you click a contact group. This method creates a new history point by calling the addHistoryPoint() method. The id of the contact group clicked is added to history.

The group id is retrieved from an expando attribute on the contact group link. The link is rendered with the following call to Ajax.ActionLink().

```
<%= Ajax.ActionLink(item.Name, "Index", new { id = item.Id }, new AjaxOptions { UpdateTargetId =
"divContactList", OnBegin = "beginContactList", OnSuccess = "successContactList", OnFailure =
"failureContactList" }, new {groupid=item.Id})%>
```

The last parameter passed to the Ajax.ActionLink() adds an expando attribute named groupid to the link (lowercase for XHTML compatibility).

When a user hits the browser Back or Forward button, the navigate event is raised and the navigate() method is called. This method updates the contacts displayed in the page to match the state of the page that corresponds to the browser history point passed to the navigate method.

Performing Ajax Deletes

Currently, in order to delete a contact, you need to click on the Delete link and then click the Delete button displayed in the delete confirmation page (see Figure 2). This seems like a lot of page requests to do something simple like deleting a database record.

Figure 02: The delete confirmation page(Click to view full-size image)

It is tempting to skip the delete confirmation page and delete a contact directly from the Index view. You should avoid this temptation because taking this approach opens your application to security holes. In general, you don t want to perform an HTTP GET operation when invoking an action that modifies the state of your web application. When performing a delete, you want to perform an HTTP POST, or better yet, an HTTP DELETE operation.

The Delete link is contained in the ContactList partial. An updated version of the ContactList partial is contained in Listing 6.

Listing 6 - Views\Contact\ContactList.ascx

```
<%@ Control Language="C#" Inherits="System.Web.Mvc.ViewUserControl<ContactManager.Models.Group>" %>
<%@ Import Namespace="Helpers" %>
<table class="data-table" cellpadding="0" cellspacing="0">
    <thead>
        <tr>
            <th class="actions edit">
                Edit
            </th>
            <th class="actions delete">
                Delete
            </th>
            <th>
                Name
            </th>
            <th>
                Phone
            </th>
            <th>
                Email
            </th>
        </tr>
    </thead>
    <tbody>
        <% foreach (var item in Model.Contacts)
           { %>
        <tr>
            <td class="actions edit">
                <a href='<%= Url.Action("Edit", new {id=item.Id}) %>'><img src="../../Content/Edit.png"
alt="Edit" /></a>
            </td>
            <td class="actions delete">
            <%= Ajax.ImageActionLink("../../Content/Delete.png", "Delete", "Delete", new { id = item.Id }, new
AjaxOptions { Confirm = "Delete contact?", HttpMethod = "Delete", UpdateTargetId = "divContactList" })%>
            </td>
            <th>
                <%= Html.Encode(item.FirstName) %>
                <%= Html.Encode(item.LastName) %>
            </th>
            <td>
                <%= Html.Encode(item.Phone) %>
            </td>
            <td>
                <%= Html.Encode(item.Email) %>
            </td>
        </tr>
        <% } %>
    </tbody>
</table>
```

The Delete link is rendered with the following call to the Ajax.ImageActionLink() method:

```
<%= Ajax.ImageActionLink("../../Content/Delete.png", "Delete", "Delete", new { id = item.Id }, new AjaxOptions
{ Confirm = "Delete contact?", HttpMethod = "Delete", UpdateTargetId = "divContactList" })%>
```

NOTE

The Ajax.ImageActionLink() is not a standard part of the ASP.NET MVC framework. The Ajax.ImageActionLink() is a custom helper methods included in the Contact Manager project.

The AjaxOptions parameter has two properties. First, the Confirm property is used to display a popup JavaScript confirmation dialog. Second, the HttpMethod property is used to perform an HTTP DELETE operation.

Listing 7 contains a new AjaxDelete() action that has been added to the Contact controller.

Listing 7 - Controllers\ContactController.cs (AjaxDelete)

```
[AcceptVerbs(HttpVerbs.Delete)]
[ActionName("Delete")]
public ActionResult AjaxDelete(int id)
{
    // Get contact and group
    var contactToDelete = _service.GetContact(id);
    var selectedGroup = _service.GetGroup(contactToDelete.Group.Id);

    // Delete from database
    _service.DeleteContact(contactToDelete);

    // Return Contact List
    return PartialView("ContactList", selectedGroup);
}
```

The AjaxDelete() action is decorated with an AcceptVerbs attribute. This attribute prevents the action from being invoked except by any HTTP operation other than an HTTP DELETE operation. In particular, you cannot invoke this action with an HTTP GET.

After you delete database record, you need to display the updated list of contacts that does not contain the deleted record. The AjaxDelete() method returns the ContactList partial and the updated list of contacts.

Summary

In this iteration, we added Ajax functionality to our Contact Manager application. We used Ajax to improve the responsiveness and performance of our application.

First, we refactored the Index view so that clicking a contact group does not update the entire view. Instead, clicking a contact group only updates the list of contacts.

Next, we used jQuery animation effects to fade out and fade in the list of contacts. Adding animation to an Ajax application can be used to provide users of the application with the equivalent of a browser progress bar.

We also added browser history support to our Ajax application. We enabled users to click the browser Back and Forward buttons to change the state of the Index view.

Finally, we created a delete link that supports HTTP DELETE operations. By performing Ajax deletes, we enable users to delete database records without requiring the user to request an additional delete confirmation page.

Iteration #1 – Create the Application (VB)

4/10/2020 • 24 minutes to read • Edit Online

by Microsoft

Download Code

> In the first iteration, we create the Contact Manager in the simplest way possible. We add support for basic database operations: Create, Read, Update, and Delete (CRUD).

Building a Contact Management ASP.NET MVC Application (VB)

In this series of tutorials, we build an entire Contact Management application from start to finish. The Contact Manager application enables you to store contact information - names, phone numbers and email addresses - for a list of people.

We build the application over multiple iterations. With each iteration, we gradually improve the application. The goal of this multiple iteration approach is to enable you to understand the reason for each change.

- Iteration #1 - Create the application. In the first iteration, we create the Contact Manager in the simplest way possible. We add support for basic database operations: Create, Read, Update, and Delete (CRUD).
- Iteration #2 - Make the application look nice. In this iteration, we improve the appearance of the application by modifying the default ASP.NET MVC view master page and cascading style sheet.
- Iteration #3 - Add form validation. In the third iteration, we add basic form validation. We prevent people from submitting a form without completing required form fields. We also validate email addresses and phone numbers.
- Iteration #4 - Make the application loosely coupled. In this fourth iteration, we take advantage of several software design patterns to make it easier to maintain and modify the Contact Manager application. For example, we refactor our application to use the Repository pattern and the Dependency Injection pattern.
- Iteration #5 - Create unit tests. In the fifth iteration, we make our application easier to maintain and modify by adding unit tests. We mock our data model classes and build unit tests for our controllers and validation logic.
- Iteration #6 - Use test-driven development. In this sixth iteration, we add new functionality to our application by writing unit tests first and writing code against the unit tests. In this iteration, we add contact groups.
- Iteration #7 - Add Ajax functionality. In the seventh iteration, we improve the responsiveness and performance of our application by adding support for Ajax.

This Iteration

In this first iteration, we build the basic application. The goal is to build the Contact Manager in the fastest and simplest way possible. In later iterations, we improve the design of the application.

The Contact Manager application is a basic database-driven application. You can use the application to create new contacts, edit existing contacts, and delete contacts.

In this iteration, we complete the following steps:

1. ASP.NET MVC application
2. Create a database to store our contacts
3. Generate a model class for our database with the Microsoft Entity Framework
4. Create a controller action and view that enables us to list all of the contacts in the database
5. Create controller actions and a view that enables us to create a new contact in the database
6. Create controller actions and a view that enables us to edit an existing contact in the database
7. Create controller actions and a view that enables us to delete an existing contact in the database

Software Prerequisites

In ASP.NET MVC applications, you must have either Visual Studio 2008 or Visual Web Developer 2008 installed on your computer (Visual Web Developer is a free version of Visual Studio that does not include all of the advanced features of Visual Studio). You can download either the trial version of Visual Studio 2008 or Visual Web Developer from the following address:

https://www.asp.net/downloads/essential/

> **NOTE**
> For ASP.NET MVC applications with Visual Web Developer, you must have Visual Web Developer Service Pack 1 installed. Without Service Pack 1, you cannot create Web Application Projects.

ASP.NET MVC framework. You can download the ASP.NET MVC framework from the following address:

https://www.asp.net/mvc

In this tutorial, we use the Microsoft Entity Framework to access a database. The Entity Framework is included with .NET Framework 3.5 Service Pack 1. You can download this service pack from the following location:

https://www.microsoft.com/downloads/details.aspx?familyid=ab99342f-5d1a-413d-8319-81da479ab0d7&displaylang=en

As an alternative to performing each of these downloads one by one, you can take advantage of the Web Platform Installer (Web PI). You can download the Web PI from the following address:

https://www.asp.net/downloads/essential/

ASP.NET MVC Project

ASP.NET MVC Web Application Project. Launch Visual Studio and select the menu option **File, New Project**. The **New Project** dialog appears (see Figure 1). Select the **Web** project type and the **ASP.NET MVC Web Application** template. Name your new project *ContactManager* and click the OK button.

Make sure that you have .NET Framework 3.5 selected from the dropdown list at the top right of the **New Project** dialog. Otherwise, the ASP.NET MVC Web Application template won't appear.

Figure 01: The New Project dialog(Click to view full-size image)

ASP.NET MVC application, the **Create Unit Test Project** dialog appears. You can use this dialog to indicate that you want to create and add a unit test project to your solution when you create your ASP.NET MVC application. Although we won't be building unit tests in this iteration, you should select the option **Yes, create a unit test project** because we plan to add unit tests in a later iteration. Adding a Test project when you first create a new ASP.NET MVC project is much easier than adding a Test project after the ASP.NET MVC project has been created.

> **NOTE**
>
> Because Visual Web Developer does not support Test projects, you do not get the Create Unit Test Project dialog when using Visual Web Developer.

Figure 02: The Create Unit Test Project dialog (Click to view full-size image)

ASP.NET MVC application appears in the Visual Studio Solution Explorer window (see Figure 3). If you don t see the Solution Explorer window then you can open this window by selecting the menu option **View, Solution Explorer**. Notice that the solution contains two projects: the ASP.NET MVC project and the Test project. The ASP.NET MVC project is named ContactManager and the Test project is named ContactManager.Tests.

Figure 03: The Solution Explorer window (Click to view full-size image)

Deleting the Project Sample Files

The ASP.NET MVC project template includes sample files for controllers and views. Before creating a new ASP.NET MVC application, you should delete these files. You can delete files and folders in the Solution Explorer window by right-clicking a file or folder and selecting the menu option **Delete**.

You need to delete the following files from the ASP.NET MVC project:

- \Controllers\HomeController.vb
- \Views\Home\About.aspx
- \Views\Home\Index.aspx

And, you need to delete the following file from the Test project:

\Controllers\HomeControllerTest.vb

Creating the Database

The Contact Manager application is a database-driven web application. We use a database to store the contact information.

The ASP.NET MVC framework with any modern database including Microsoft SQL Server, Oracle, MySQL, and IBM DB2 databases. In this tutorial, we use a Microsoft SQL Server database. When you install Visual Studio, you are provided with the option of installing Microsoft SQL Server Express which is a free version of the Microsoft SQL Server database.

Create a new database by right-clicking the App_Data folder in the Solution Explorer window and selecting the menu option **Add, New Item**. In the **Add New Item** dialog, select the **Data** category and the **SQL Server Database** template (see Figure 4). Name the new database ContactManagerDB.mdf and click the OK button.

Figure 04: Creating a new Microsoft SQL Server Express database (Click to view full-size image)

After you create the new database, the database appears in the App_Data folder in the Solution Explorer window. Double-click the ContactManager.mdf file to open the Server Explorer window and connect to the database.

> **NOTE**
>
> The Server Explorer window is called the Database Explorer window in the case of Microsoft Visual Web Developer.

You can use the Server Explorer window to create new database objects such as database tables, views, triggers, and stored procedures. Right-click the Tables folder and select the menu option **Add New Table**. The Database Table Designer appears (see Figure 5).

Figure 05: The Database Table Designer (Click to view full-size image)

We need to create a table that contains the following columns:

COLUMN NAME	DATA TYPE	ALLOW NULLS
Id	int	false
FirstName	nvarchar(50)	false
LastName	nvarchar(50)	false
Phone	nvarchar(50)	false

COLUMN NAME	DATA TYPE	ALLOW NULLS
Email	nvarchar(255)	false

The first column, the Id column, is special. You need to mark the Id column as an Identity column and a Primary Key column. You indicate that a column is an Identity column by expanding Column Properties (look at the bottom of Figure 6) and scrolling down to the Identity Specification property. Set the **(Is Identity)** property to the value **Yes**.

You mark a column as a Primary Key column by selecting the column and clicking the button with the icon of a key. After a column is marked as a Primary Key column, an icon of a key appears next to the column (see Figure 6).

After you finish creating the table, click the Save button (the button with an icon of a floppy) to save the new table. Give your new table the name *Contacts*.

After finish creating the Contacts database table, you should add some records to the table. Right-click the Contacts table in the Server Explorer window and select the menu option **Show Table Data**. Enter one or more contacts in the grid that appears.

Creating the Data Model

The ASP.NET MVC application consists of Models, Views, and Controllers. We start by creating a Model class that represents the Contacts table that we created in the previous section.

In this tutorial, we use the Microsoft Entity Framework to generate a model class from the database automatically.

> **NOTE**
> The ASP.NET MVC framework is not tied to the Microsoft Entity Framework in any way. You can use ASP.NET MVC with alternative database access technologies including NHibernate, LINQ to SQL, or ADO.NET.

Follow these steps to create the data model classes:

1. Right-click the Models folder in the Solution Explorer window and select **Add, New Item**. The **Add New Item** dialog appears (see Figure 6).
2. Select the **Data** category and the **ADO.NET Entity Data Model** template. Name your data model *ContactManagerModel.edmx* and click the **Add** button. The Entity Data Model wizard appears (see Figure 7).
3. In the **Choose Model Contents** step, select **Generate from database** (see Figure 7).
4. In the **Choose Your Data Connection** step, select the ContactManagerDB.mdf database and enter the name *ContactManagerDBEntities* for the Entity Connection Settings (see Figure 8).
5. In the **Choose Your Database Objects** step, select the checkbox labeled Tables (see Figure 9). The data model will include all tables contained in your database (there is just one, the Contacts table). Enter the namespace *Models*. Click the Finish button to complete the wizard.

Figure 06: The Add New Item dialog (Click to view full-size image)

Figure 07: Choose Model Contents (Click to view full-size image)

Figure 08: Choose Your Data Connection (Click to view full-size image)

Figure 09: Choose Your Database Objects (Click to view full-size image)

After you complete the Entity Data Model Wizard, the Entity Data Model Designer appears. The designer displays a class that corresponds to each table being modeled. You should see one class named Contacts.

The Entity Data Model wizard generates class names based on database table names. You almost always need to change the name of the class generated by the wizard. Right-click the Contacts class in the designer and select the menu option **Rename**. Change the name of the class from Contacts (plural) to Contact (singular). After you change the class name, the class should appear like Figure 10.

Figure 10: The Contact class (Click to view full-size image)

At this point, we have created our database model. We can use the Contact class to represent a particular contact record in our database.

Creating the Home Controller

The next step is to create our Home controller. The Home controller is the default controller invoked in an ASP.NET MVC application.

Create the Home controller class by right-clicking the Controllers folder in the Solution Explorer window and selecting the menu option **Add, Controller** (see Figure 11). Notice the checkbox labeled **Add action methods for Create, Update, and Details scenarios**. Make sure that this checkbox is checked before clicking the **Add** button.

Figure 11: Adding the Home controller (Click to view full-size image)

When you create the Home controller, you get the class in Listing 1.

Listing 1 - Controllers\HomeController.vb

```
Public Class HomeController
    Inherits System.Web.Mvc.Controller

    '
    ' GET: /Home/

    Function Index() As ActionResult
        Return View()
    End Function

    '
    ' GET: /Home/Details/5

    Function Details(ByVal id As Integer) As ActionResult
        Return View()
    End Function

    '
    ' GET: /Home/Create

    Function Create() As ActionResult
        Return View()
    End Function

    '
    ' POST: /Home/Create

    <AcceptVerbs(HttpVerbs.Post)> _
    Function Create(ByVal collection As FormCollection) As ActionResult
        Try
            ' TODO: Add insert logic here
            Return RedirectToAction("Index")
        Catch
            Return View()
        End Try
    End Function

    '
    ' GET: /Home/Edit/5

    Function Edit(ByVal id As Integer) As ActionResult
        Return View()
    End Function

    '
    ' POST: /Home/Edit/5

    <AcceptVerbs(HttpVerbs.Post)> _
    Function Edit(ByVal id As Integer, ByVal collection As FormCollection) As ActionResult
        Try
            ' TODO: Add update logic here

            Return RedirectToAction("Index")
        Catch
            Return View()
        End Try
    End Function
End Class
```

Listing the Contacts

In order to display the records in the Contacts database table, we need to create an Index() action and an Index view.

The Home controller already contains an Index() action. We need to modify this method so that it looks like Listing

2.

Listing 2 - Controllers\HomeController.vb

```
Public Class HomeController
    Inherits System.Web.Mvc.Controller

    Private _entities As New ContactManagerDBEntities()

    '
    ' GET: /Home/

    Function Index() As ActionResult
        Return View(_entities.ContactSet.ToList())
    End Function
…
```

Notice that the Home controller class in Listing 2 contains a private field named _entities. The _entities field represents the entities from the data model. We use the _entities field to communicate with the database.

The Index() method returns a view that represents all of the contacts from the Contacts database table. The expression _entities.ContactSet.ToList() returns the list of contacts as a generic list.

Now that we ve created the Index controller, we next need to create the Index view. Before creating the Index view, compile your application by selecting the menu option **Build, Build Solution**. You should always compile your project before adding a view in order for the list of model classes to be displayed in the **Add View** dialog.

You create the Index view by right-clicking the Index() method and selecting the menu option **Add View** (see Figure 12). Selecting this menu option opens the **Add View** dialog (see Figure 13).

Figure 12: Adding the Index view (Click to view full-size image)

In the **Add View** dialog, check the checkbox labeled **Create a strongly-typed view**. Select the View data class ContactManager.Contact and the View content List. Selecting these options generates a view that displays a list of Contact records.

Figure 13: The Add View dialog (Click to view full-size image)

When you click the **Add** button, the Index view in Listing 3 is generated. Notice the <%@ Page %> directive that appears at the top of the file. The Index view inherits from the ViewPage<IEnumerable<ContactManager.Models.Contact>> class. In other words, the Model class in the view represents a list of Contact entities.

The body of the Index view contains a foreach loop that iterates through each of the contacts represented by the Model class. The value of each property of the Contact class is displayed within an HTML table.

Listing 3 - Views\Home\Index.aspx (unmodified)

```
<%@ Page Title="" Language="VB" MasterPageFile="~/Views/Shared/Site.Master"
Inherits="System.Web.Mvc.ViewPage(Of IEnumerable(Of ContactManager.Contact))" %>

<asp:Content ID="Content1" ContentPlaceHolderID="head" runat="server">
<title>Index</title>
</asp:Content>

<asp:Content ID="Content2" ContentPlaceHolderID="MainContent" runat="server">

    <h2>Index</h2>

    <p>
        <%=Html.ActionLink("Create New", "Create")%>
    </p>

    <table>
        <tr>
            <th></th>
            <th>
                Id
            </th>
            <th>
                FirstName
            </th>
            <th>
                LastName
            </th>
            <th>
                Phone
            </th>
            <th>
                Email
            </th>
        </tr>

    <% For Each item In Model%>

        <tr>
            <td>
                <%=Html.ActionLink("Edit", "Edit", New With {.id = item.Id})%> |
                <%=Html.ActionLink("Details", "Details", New With {.id = item.Id})%>
            </td>
            <td>
                <%=Html.Encode(item.Id)%>
            </td>
            <td>
                <%=Html.Encode(item.FirstName)%>
            </td>
            <td>
                <%=Html.Encode(item.LastName)%>
            </td>
            <td>
                <%=Html.Encode(item.Phone)%>
            </td>
            <td>
                <%=Html.Encode(item.Email)%>
            </td>
        </tr>

    <% Next%>

    </table>

</asp:Content>
```

We need to make one modification to the Index view. Because we are not creating a Details view, we can remove

the Details link. Find and remove the following code from the Index view:

{.id = item.Id})%>

After you modify the Index view, you can run the Contact Manager application. Select the menu option Debug, Start Debugging or simply press F5. The first time you run the application, you get the dialog in Figure 14. Select the option **Modify the Web.config file to enable debugging** and click the OK button.

Figure 14: Enabling debugging (Click to view full-size image)

The Index view is returned by default. This view lists all of the data from the Contacts database table (see Figure 15).

Figure 15: The Index view (Click to view full-size image)

Notice that the Index view includes a link labeled Create New at the bottom of the view. In the next section, you learn how to create new contacts.

Creating New Contacts

To enable users to create new contacts, we need to add two Create() actions to the Home controller. We need to create one Create() action that returns an HTML form for creating a new contact. We need to create a second Create() action that performs the actual database insert of the new contact.

The new Create() methods that we need to add to the Home controller are contained in Listing 4.

Listing 4 - Controllers\HomeController.vb (with Create methods)

```
'
' GET: /Home/Create

Function Create() As ActionResult
    Return View()
End Function

'
' POST: /Home/Create

<AcceptVerbs(HttpVerbs.Post)> _
Function Create(<Bind(Exclude:="Id")> ByVal contactToCreate As Contact) As ActionResult
    If Not ModelState.IsValid Then
        Return View()
    End If

    Try
        _entities.AddToContactSet(contactToCreate)
        _entities.SaveChanges()
        Return RedirectToAction("Index")
    Catch
        Return View()
    End Try
End Function
```

The first Create() method can be invoked with an HTTP GET while the second Create() method can be invoked only by an HTTP POST. In other words, the second Create() method can be invoked only when posting an HTML form. The first Create() method simply returns a view that contains the HTML form for creating a new contact. The second Create() method is much more interesting: it adds the new contact to the database.

Notice that the second Create() method has been modified to accept an instance of the Contact class. The form values posted from the HTML form are bound to this Contact class by the ASP.NET MVC framework automatically. Each form field from the HTML Create form is assigned to a property of the Contact parameter.

Notice that the Contact parameter is decorated with a [Bind] attribute. The [Bind] attribute is used to exclude the Contact Id property from binding. Because the Id property represents an Identity property, we don t want to set the Id property.

In the body of the Create() method, the Entity Framework is used to insert the new Contact into the database. The new Contact is added to the existing set of Contacts and the SaveChanges() method is called to push these changes back to the underlying database.

You can generate an HTML form for creating new Contacts by right-clicking either of the two Create() methods and selecting the menu option **Add View** (see Figure 16).

Figure 16: Adding the Create view (Click to view full-size image)

In the **Add View** dialog, select the **ContactManager.Contact** class and the **Create** option for view content (see Figure 17). When you click the **Add** button, a Create view is generated automatically.

Figure 17: Seeing a page explode (Click to view full-size image)

The Create view contains form fields for each of the properties of the Contact class. The code for the Create view is included in Listing 5.

Listing 5 - Views\Home\Create.aspx

```
<%@ Page Title="" Language="VB" MasterPageFile="~/Views/Shared/Site.Master"
Inherits="System.Web.Mvc.ViewPage(Of ContactManager.Contact)" %>

<asp:Content ID="Content1" ContentPlaceHolderID="head" runat="server">
<title>Create</title>
</asp:Content>

<asp:Content ID="Content2" ContentPlaceHolderID="MainContent" runat="server">

    <h2>Create</h2>

    <%= Html.ValidationSummary() %>

    <% Using Html.BeginForm()%>

        <fieldset>
            <legend>Fields</legend>
            <p>
                <label for="FirstName">FirstName:</label>
                <%= Html.TextBox("FirstName") %>
                <%= Html.ValidationMessage("FirstName", "*") %>
            </p>
            <p>
                <label for="LastName">LastName:</label>
                <%= Html.TextBox("LastName") %>
                <%= Html.ValidationMessage("LastName", "*") %>
            </p>
            <p>
                <label for="Phone">Phone:</label>
                <%= Html.TextBox("Phone") %>
                <%= Html.ValidationMessage("Phone", "*") %>
            </p>
            <p>
                <label for="Email">Email:</label>
                <%= Html.TextBox("Email") %>
                <%= Html.ValidationMessage("Email", "*") %>
            </p>
            <p>
                <input type="submit" value="Create" />
            </p>
        </fieldset>

    <% End Using %>

    <div>
        <%=Html.ActionLink("Back to List", "Index") %>
    </div>

</asp:Content>
```

After you modify the Create() methods and add the Create view, you can run the Contact Manger application and create new contacts. Click the **Create New** link that appears in the Index view to navigate to the Create view. You should see the view in Figure 18.

Figure 18: The Create View (Click to view full-size image)

Editing Contacts

Adding the functionality for editing a contact record is very similar to adding the functionality for creating new contact records. First, we need to add two new Edit methods to the Home controller class. These new Edit() methods are contained in Listing 6.

Listing 6 - Controllers\HomeController.vb (with Edit methods)

```
'
' GET: /Home/Edit/5

Function Edit(ByVal id As Integer) As ActionResult
    Dim contactToEdit = (from c in _entities.ContactSet _
                        where c.Id = id _
                        select c).FirstOrDefault()

    Return View(contactToEdit)
End Function

'
' POST: /Home/Edit/5

<AcceptVerbs(HttpVerbs.Post)> _
Function Edit(ByVal contactToEdit As Contact) As ActionResult
    If Not ModelState.IsValid Then
        Return View()
    End If

    Try
        Dim originalContact = (from c in _entities.ContactSet _
                              where c.Id = contactToEdit.Id _
                              select c).FirstOrDefault()
        _entities.ApplyPropertyChanges( originalContact.EntityKey.EntitySetName, contactToEdit)
        _entities.SaveChanges()
        Return RedirectToAction("Index")
    Catch
        Return View()
    End Try
End Function
```

The first Edit() method is invoked by an HTTP GET operation. An Id parameter is passed to this method which represents the Id of the contact record being edited. The Entity Framework is used to retrieve a contact that

matches the Id. A view that contains an HTML form for editing a record is returned.

The second Edit() method performs the actual update to the database. This method accepts an instance of the Contact class as a parameter. The ASP.NET MVC framework binds the form fields from the Edit form to this class automatically. Notice that you don t include the[Bind] attribute when editing a Contact (we need the value of the Id property).

The Entity Framework is used to save the modified Contact to the database. The original Contact must be retrieved from the database first. Next, the Entity Framework ApplyPropertyChanges() method is called to record the changes to the Contact. Finally, the Entity Framework SaveChanges() method is called to persist the changes to the underlying database.

You can generate the view that contains the Edit form by right-clicking the Edit() method and selecting the menu option Add View. In the Add View dialog, select the **ContactManager.Models.Contact** class and the **Edit** view content (see Figure 19).

Figure 19: Adding an Edit View (Click to view full-size image)

When you click the Add button, a new Edit view is generated automatically. The HTML form that is generated contains fields that correspond to each of the properties of the Contact class (see Listing 7).

Listing 7 - Views\Home\Edit.aspx

```
<%@ Page Title="" Language="VB" MasterPageFile="~/Views/Shared/Site.Master"
Inherits="System.Web.Mvc.ViewPage(Of ContactManager.Contact)" %>

<asp:Content ID="Content1" ContentPlaceHolderID="head" runat="server">
<title>Edit</title>
</asp:Content>

<asp:Content ID="Content2" ContentPlaceHolderID="MainContent" runat="server">

    <h2>Edit</h2>

    <%=Html.ValidationSummary()%>

    <% Using Html.BeginForm() %>

        <fieldset>
            <legend>Fields</legend>
            <p>
                <label for="FirstName">FirstName:</label>
                <%= Html.TextBox("FirstName") %>
                <%= Html.ValidationMessage("FirstName", "*") %>
            </p>
            <p>
                <label for="LastName">LastName:</label>
                <%= Html.TextBox("LastName") %>
                <%= Html.ValidationMessage("LastName", "*") %>
            </p>
            <p>
                <label for="Phone">Phone:</label>
                <%= Html.TextBox("Phone") %>
                <%= Html.ValidationMessage("Phone", "*") %>
            </p>
            <p>
                <label for="Email">Email:</label>
                <%= Html.TextBox("Email") %>
                <%= Html.ValidationMessage("Email", "*") %>
            </p>
            <p>
                <input type="submit" value="Save" />
            </p>
        </fieldset>

    <% End Using %>

    <div>
        <%=Html.ActionLink("Back to List", "Index") %>
    </div>

</asp:Content>
```

Deleting Contacts

If you want to delete contacts then you need to add two Delete() actions to the Home controller class. The first Delete() action displays a delete confirmation form. The second Delete() action performs the actual delete.

> **NOTE**
>
> Later, in Iteration #7, we modify the Contact Manager so that it supports a one step Ajax delete.

The two new Delete() methods are contained in Listing 8.

Listing 8 - Controllers\HomeController.vb (Delete methods)

```
'
' GET: /Home/Delete/5

Function Delete(ByVal id As Integer) As ActionResult
    Dim contactToDelete = (from c in _entities.ContactSet _
                        where c.Id = id _
                        select c).FirstOrDefault()

    Return View(contactToDelete)
End Function

'
' POST: /Home/Delete/5

<AcceptVerbs(HttpVerbs.Post)> _
Function Delete(ByVal contactToDelete As Contact) As ActionResult
    Try
        Dim originalContact = (from c in _entities.ContactSet _
                            where c.Id = contactToDelete.Id _
                            select c).FirstOrDefault()
        _entities.DeleteObject(originalContact)
        _entities.SaveChanges()
        Return RedirectToAction("Index")
    Catch
        Return View()
    End Try
End Function
```

The first Delete() method returns a confirmation form for deleting a contact record from the database (see Figure20). The second Delete() method performs the actual delete operation against the database. After the original contact has been retrieved from the database, the Entity Framework DeleteObject() and SaveChanges() methods are called to perform the database delete.

Figure 20: The delete confirmation view (Click to view full-size image)

We need to modify the Index view so that it contains a link for deleting contact records (see Figure 21). You need to add the following code to the same table cell that contains the Edit link:

{.id = item.Id})%>

Figure 21: Index view with Edit link (Click to view full-size image)

Next, we need to create the delete confirmation view. Right-click the Delete() method in the Home controller class and select the menu option Add View. The Add View dialog appears (see Figure 22).

Unlike in the case of the List, Create, and Edit views, the Add View dialog does not contain an option to create a Delete view. Instead, select the **ContactManager.Models.Contact** data class and the **Empty** view content. Selecting the Empty view content option will require us to create the view ourselves.

Figure 22: Adding the delete confirmation view (Click to view full-size image)

The content of the Delete view is contained in Listing 9. This view contains a form that confirms whether or not a particular contact should be deleted (see Figure 21).

Listing 9 - Views\Home\Delete.aspx

```
<%@ Page Title="" Language="VB" MasterPageFile="~/Views/Shared/Site.Master"
Inherits="System.Web.Mvc.ViewPage(Of ContactManager.Contact)" %>

<asp:Content ID="Content1" ContentPlaceHolderID="head" runat="server">
<title>Delete</title>
</asp:Content>

<asp:Content ID="Content2" ContentPlaceHolderID="MainContent" runat="server">

    <h2>Delete</h2>

    <p>
    Are you sure that you want to delete the entry for
    <%= Model.FirstName %> <%= Model.LastName %>?
    </p>

    <% Using Html.BeginForm(New With { .Id = Model.Id }) %>
       <p>
            <input type="submit" value="Delete" />
        </p>
    <% End Using %>

    <div>
        <%=Html.ActionLink("Back to List", "Index") %>
    </div>

</asp:Content>
```

Changing the Name of the Default Controller

It might bother you that the name of our controller class for working with contacts is named the HomeController class. Shouldn't the controller be named ContactController?

This issue is easy enough to fix. First, we need to refactor the name of the Home controller. Open the HomeController class in the Visual Studio Code Editor, right click the name of the class and select the menu option **Rename**. Selecting this menu option opens the Rename dialog.

Figure 23: Refactoring a controller name (Click to view full-size image)

Figure 24: Using the Rename dialog (Click to view full-size image)

If you rename your controller class, Visual Studio will update the name of the folder in the Views folder as well. Visual Studio will rename the \Views\Home folder to the \Views\Contact folder.

After you make this change, your application will no longer have a Home controller. When you run your application, you'll get the error page in Figure 25.

Figure 25: No default controller (Click to view full-size image)

We need to update the default route in the Global.asax file to use the Contact controller instead of the Home controller. Open the Global.asax file and modify the default controller used by the default route (see Listing 10).

Listing 10 - Global.asax.vb

```
Public Class MvcApplication
    Inherits System.Web.HttpApplication

    Shared Sub RegisterRoutes(ByVal routes As RouteCollection)
        routes.IgnoreRoute("{resource}.axd/{*pathInfo}")

        ' MapRoute takes the following parameters, in order:
        ' (1) Route name
        ' (2) URL with parameters
        ' (3) Parameter defaults
        routes.MapRoute( _
            "Default", _
            "{controller}/{action}/{id}", _
            New With {.controller = "Home", .action = "Index", .id = ""} _
        )

    End Sub

    Sub Application_Start()
        RegisterRoutes(RouteTable.Routes)
    End Sub
End Class
```

After you make these changes, the Contact Manager will run correctly. Now, it will use the Contact controller class as the default controller.

Summary

In this first iteration, we created a basic Contact Manager application in the fastest way possible. We took advantage of Visual Studio to generate the initial code for our controllers and views automatically. We also took advantage of the Entity Framework to generate our database model classes automatically.

Currently, we can list, create, edit, and delete contact records with the Contact Manager application. In other words, we can perform all of the basic database operations required by a database-driven web application.

Unfortunately, our application has some problems. First and I hesitate to admit this, the Contact Manager application is not the most attractive application. It needs some design work. In the next iteration, we'll look at how we can change the default view master page and cascading style sheet to improve the appearance of the application.

Second, we have not implemented any form validation. For example, there is nothing to prevent you from submitting the Create contact form without entering values for any of the form fields. Furthermore, you can enter invalid phone numbers and email addresses. We start to tackle the problem of form validation in iteration #3.

Finally, and most importantly, the current iteration of the Contact Manager application cannot be easily modified or maintained. For example, the database access logic is baked right into the controller actions. This means that we cannot modify our data access code without modifying our controllers. In later iterations, we explore software design patterns that we can implement to make the Contact Manager more resilient to change.

Iteration #2 – Make the application look nice (VB)

4/10/2020 • 8 minutes to read • Edit Online

by Microsoft

Download Code

> In this iteration, we improve the appearance of the application by modifying the default ASP.NET MVC view master page and cascading style sheet.

Building a Contact Management ASP.NET MVC Application (VB)

In this series of tutorials, we build an entire Contact Management application from start to finish. The Contact Manager application enables you to store contact information – names, phone numbers and email addresses – for a list of people.

We build the application over multiple iterations. With each iteration, we gradually improve the application. The goal of this multiple iteration approach is to enable you to understand the reason for each change.

- Iteration #1 – Create the application. In the first iteration, we create the Contact Manager in the simplest way possible. We add support for basic database operations: Create, Read, Update, and Delete (CRUD).
- Iteration #2 – Make the application look nice. In this iteration, we improve the appearance of the application by modifying the default ASP.NET MVC view master page and cascading style sheet.
- Iteration #3 – Add form validation. In the third iteration, we add basic form validation. We prevent people from submitting a form without completing required form fields. We also validate email addresses and phone numbers.
- Iteration #4 – Make the application loosely coupled. In this fourth iteration, we take advantage of several software design patterns to make it easier to maintain and modify the Contact Manager application. For example, we refactor our application to use the Repository pattern and the Dependency Injection pattern.
- Iteration #5 – Create unit tests. In the fifth iteration, we make our application easier to maintain and modify by adding unit tests. We mock our data model classes and build unit tests for our controllers and validation logic.
- Iteration #6 – Use test-driven development. In this sixth iteration, we add new functionality to our application by writing unit tests first and writing code against the unit tests. In this iteration, we add contact groups.
- Iteration #7 – Add Ajax functionality. In the seventh iteration, we improve the responsiveness and performance of our application by adding support for Ajax.

This Iteration

The goal of this iteration is to improve the appearance of the Contact Manager application. Currently, the Contact Manager uses the default ASP.NET MVC view master page and cascading style sheet (see Figure 1). These don t look bad, but I don t want the Contact Manager to look just like every other ASP.NET MVC website. I want to replace these files with custom files.

Figure 01: The default appearance of an ASP.NET MVC Application (Click to view full-size image)

In this iteration, I discuss two approaches to improving the visual design of our application. First, I show you how to take advantage of the ASP.NET MVC Design gallery to download a free ASP.NET MVC design template. The ASP.NET MVC Design gallery enables you to create a professional web application without doing any work.

I decided to not use a template from the ASP.NET MVC Design gallery for the Contact Manager application. Instead, I had a custom design created by a professional design firm. In the second part of this tutorial, I explain how I worked with a professional design company to create the final ASP.NET MVC design.

The ASP.NET MVC Design Gallery

The ASP.NET MVC Design Gallery is a free resource provided by Microsoft. The ASP.NET MVC Gallery is located at the following address:

https://www.asp.net/mvc/gallery

The ASP.NET MVC Design Gallery hosts a collection of free website designs that were created specifically for using in an ASP.NET MVC project. Designs are uploaded by members of the community. Visitors to the Gallery can vote for their favorite designs (see Figure 2).

Figure 02: The ASP.NET MVC Design Gallery (Click to view full-size image)

As I write this tutorial, the most popular design in the gallery is a design named October by David Hauser. You can use this design for an ASP.NET MVC project by completing the following steps:

1. Click the **Download** button to download the October.zip file to your computer.
2. Right-click the downloaded October.zip file and click the **Unblock** button (see Figure 3).
3. Unzip the file to a folder named October.
4. Select all of the files from the DesignTemplate folder contained in the October folder, right-click the files, and select the menu option **Copy**.

5. Right-click the ContactManager project node in the Visual Studio Solution Explorer window and select the menu option **Paste** (see Figure 4).
6. Select the Visual Studio menu option **Edit, Find and Replace, Quick Replace** and replace *[MyProjectName]* with *ContactManager* (see Figure 5).

Figure 03: Unblocking a file downloaded from the web (Click to view full-size image)

Figure 04: Overwriting files in the Solution Explorer (Click to view full-size image)

Figure 05: Replacing [ProjectName] with ContactManager (Click to view full-size image)

After you complete these steps, your web application will use the new design. The page in Figure 6 illustrates the appearance of the Contact Manager application with the October design.

Figure 06: ContactManager with the October template (Click to view full-size image)

Creating a Custom ASP.NET MVC Design

The ASP.NET MVC Design Gallery has a good selection of different design styles. The Gallery provides you with a painless way to customize the appearance of your ASP.NET MVC applications. And, of course, the Gallery has the big advantage of being completely free.

However, you might need to create a completely unique design for your website. In that case, it makes sense to work with a website design company. I decided to take this approach for the design for the Contact Manager application.

I zipped up the Contact Manager from Iteration #1 and sent the project to the design company. They did not own Visual Studio (shame on them!), but that didn't present a problem. They were able to download Microsoft Visual Web Developer for free from the https://www.asp.net website and open the Contact Manager application in Visual Web Developer. In a couple of days, they had produced the design in Figure 7.

Figure 07: The ASP.NET MVC Contact Manager Design (Click to view full-size image)

The new design consisted of two main files: a new cascading style sheet file and a new view master page file. A view master page contains the layout and shared content for views in an ASP.NET MVC application. For example, the view master page includes the header, navigation tabs, and footer that appear in Figure 7. I overwrote the existing Site.Master view master page in the Views\Shared folder with the new Site.Master file from the design company,

The design company also created a new cascading style sheet and set of images. I placed these new files in the Content folder and overwrote the existing Site.css file. You should place all static content in the Content folder.

Notice that the new design for the Contact Manager includes images for editing and deleting contacts. An Edit and Delete image appear next to each contact in the HTML table of contacts.

Originally, these links that were rendered with the HTML.ActionLink() helper like this:

```
<td>
    <%= Html.ActionLink("Edit", "Edit", new { id=item.Id  }) %> |
    <%= Html.ActionLink("Delete", "Delete", new { id=item.Id  }) %>
</td>
```

The Html.ActionLink() method does not support images (the method HTML encodes the link text for security reasons). Therefore, I replaced the calls to Html.ActionLink() with calls to Url.Action() like this:

```
<td class="actions edit">
    <a href='<%= Url.Action("Edit", new {id=item.Id}) %>'><img src="../../Content/Edit.png" alt="Edit" /></a>
</td>
<td class="actions delete">
    <a href='<%= Url.Action("Delete", new {id=item.Id}) %>'><img src="../../Content/Delete.png" alt="Delete"
/></a>
</td>
```

The Html.ActionLink() method renders an entire HTML hyperlink. The Url.Action() method, on the other hand, renders just the URL without the <a> tag.

Notice, furthermore, that the new design includes both selected and unselected tabs. For example, in Figure 8, the **Create New Contact** tab is selected and the **My Contacts** tab is not selected.

Figure 08: Selected and unselected tabs(Click to view full-size image)

To support rendering both selected and unselected tabs, I created a custom HTML helper named the MenuItemHelper. This helper method renders either a <li> tag or a <li class="selected"> tag depending on whether the current controller and action corresponds to the controller and action name passed to the helper. The code for the MenuItemHelper is contained in Listing 1.

Listing 1 – Helpers\MenuItemHelper.vb

```
Public Module MenuItemHelper

   <System.Runtime.CompilerServices.Extension> _
   Function MenuItem(ByVal helper As HtmlHelper, ByVal linkText As String, ByVal actionName As String, ByVal
controllerName As String) As String
        Dim currentControllerName As String = helper.ViewContext.RouteData.Values("controller")
        Dim currentActionName As String = helper.ViewContext.RouteData.Values("action")

        Dim builder = New TagBuilder("li")

        ' Add selected class
        If currentControllerName.Equals(controllerName, StringComparison.CurrentCultureIgnoreCase) AndAlso
currentActionName.Equals(actionName, StringComparison.CurrentCultureIgnoreCase) Then
            builder.AddCssClass("selected")
        End If

        ' Add link
        builder.InnerHtml = helper.ActionLink(linkText, actionName, controllerName)

        ' Render Tag Builder
        Return builder.ToString(TagRenderMode.Normal)
   End Function

End Module
```

The MenuItemHelper uses the TagBuilder class internally to build the <li> HTML tag. The TagBuilder class is a very useful utility class that you can use whenever you need to build up a new HTML tag. It includes methods for adding attributes, adding CSS classes, generating Ids, and modifying the tag s inner HTML.

Summary

In this iteration, we improved the visual design of our ASP.NET MVC application. First, you were introduced to the ASP.NET MVC Design Gallery. You learned how to download free design templates from the ASP.NET MVC Design Gallery that you can use in your ASP.NET MVC applications.

Next, we discussed how you can create a custom design by modifying the default cascading style sheet file and master view page file. In order to support the new design, we had to make some minor changes to our Contact Manager application. For example, we added a new HTML helper named the MenuItemHelper that displays selected and unselected tabs.

In the next iteration, we tackle the very important subject of validation. We add validation code to our application so that a user cannot create a new contact without supplying required values such as a person s first and last name.

> In the third iteration, we add basic form validation. We prevent people from submitting a form without completing required form fields. We also validate email addresses and phone numbers.

Building a Contact Management ASP.NET MVC Application (VB)

In this series of tutorials, we build an entire Contact Management application from start to finish. The Contact Manager application enables you to store contact information - names, phone numbers and email addresses - for a list of people.

We build the application over multiple iterations. With each iteration, we gradually improve the application. The goal of this multiple iteration approach is to enable you to understand the reason for each change.

- Iteration #1 - Create the application. In the first iteration, we create the Contact Manager in the simplest way possible. We add support for basic database operations: Create, Read, Update, and Delete (CRUD).
- Iteration #2 - Make the application look nice. In this iteration, we improve the appearance of the application by modifying the default ASP.NET MVC view master page and cascading style sheet.
- Iteration #3 - Add form validation. In the third iteration, we add basic form validation. We prevent people from submitting a form without completing required form fields. We also validate email addresses and phone numbers.
- Iteration #4 - Make the application loosely coupled. In this fourth iteration, we take advantage of several software design patterns to make it easier to maintain and modify the Contact Manager application. For example, we refactor our application to use the Repository pattern and the Dependency Injection pattern.
- Iteration #5 - Create unit tests. In the fifth iteration, we make our application easier to maintain and modify by adding unit tests. We mock our data model classes and build unit tests for our controllers and validation logic.
- Iteration #6 - Use test-driven development. In this sixth iteration, we add new functionality to our application by writing unit tests first and writing code against the unit tests. In this iteration, we add contact groups.
- Iteration #7 - Add Ajax functionality. In the seventh iteration, we improve the responsiveness and performance of our application by adding support for Ajax.

This Iteration

In this second iteration of the Contact Manager application, we add basic form validation. We prevent people from submitting a contact without entering values for required form fields. We also validate phone numbers and email addresses (see Figure 1).

Figure 01: A form with validation (Click to view full-size image)

In this iteration, we add the validation logic directly to the controller actions. In general, this is not the recommended way to add validation to an ASP.NET MVC application. A better approach is to place an application s validation logic in a separate service layer. In the next iteration, we refactor the Contact Manager application to make the application more maintainable.

In this iteration, to keep things simple, we write all of the validation code by hand. Instead of writing the validation code ourselves, we could take advantage of a validation framework. For example, you can use the Microsoft Enterprise Library Validation Application Block (VAB) to implement the validation logic for your ASP.NET MVC application. To learn more about the Validation Application Block, see:

http://msdn.microsoft.com/library/dd203099.aspx

Adding Validation to the Create View

Let s start by adding validation logic to the Create view. Fortunately, because we generated the Create view with Visual Studio, the Create view already contains all of the necessary user interface logic to display validation messages. The Create view is contained in Listing 1.

Listing 1 - \Views\Contact\Create.aspx

```
<%@ Page Title="" Language="VB" MasterPageFile="~/Views/Shared/Site.Master"
Inherits="System.Web.Mvc.ViewPage(Of ContactManager.Contact)" %>

<asp:Content ID="Content1" ContentPlaceHolderID="head" runat="server">
<title>Create</title>
</asp:Content>

<asp:Content ID="Content2" ContentPlaceHolderID="MainContent" runat="server">

    <%= Html.ValidationSummary() %>

    <% Using Html.BeginForm()%>

        <fieldset>
            <legend>Create New Contact</legend>
            <p>
                <label for="FirstName">First Name:</label>
                <%= Html.TextBox("FirstName") %>
                <%= Html.ValidationMessage("FirstName", "*") %>
            </p>
            <p>
                <label for="LastName">Last Name:</label>
                <%= Html.TextBox("LastName") %>
                <%= Html.ValidationMessage("LastName", "*") %>
            </p>
            <p>
                <label for="Phone">Phone:</label>
                <%= Html.TextBox("Phone") %>
                <%= Html.ValidationMessage("Phone", "*") %>
            </p>
            <p>
                <label for="Email">Email:</label>
                <%= Html.TextBox("Email") %>
                <%= Html.ValidationMessage("Email", "*") %>
            </p>
            <p class="submit">
                <input type="submit" value="Create" />
            </p>
        </fieldset>

    <% End Using %>

</asp:Content>
```

The field-validation-error class is used to style the output rendered by the Html.ValidationMessage() helper. The input-validation-error class is used to style the textbox (input) rendered by the Html.TextBox() helper. The validation-summary-errors class is used to style the unordered list rendered by the Html.ValidationSummary() helper.

> **NOTE**
> You can modify the style sheet classes described in this section to customize the appearance of validation error messages.

Adding Validation Logic to the Create Action

Right now, the Create view never displays validation error messages because we have not written the logic to generate any messages. In order to display validation error messages, you need to add the error messages to ModelState.

> **NOTE**
> The UpdateModel() method adds error messages to ModelState automatically when there is an error assigning the value of a form field to a property. For example, if you attempt to assign the string "apple" to a BirthDate property that accepts DateTime values, then the UpdateModel() method adds an error to ModelState.

The modified Create() method in Listing 2 contains a new section that validates the properties of the Contact class before the new contact is inserted into the database.

Listing 2 - Controllers\ContactController.vb (Create with validation)

```
<AcceptVerbs(HttpVerbs.Post)> _
Function Create(<Bind(Exclude:="Id")> ByVal contactToCreate As Contact) As ActionResult
    ' Validation logic
    If contactToCreate.FirstName.Trim().Length = 0 Then
        ModelState.AddModelError("FirstName", "First name is required.")
    End If
    If contactToCreate.LastName.Trim().Length = 0 Then
        ModelState.AddModelError("LastName", "Last name is required.")
    End If
    If (contactToCreate.Phone.Length > 0 AndAlso Not Regex.IsMatch(contactToCreate.Phone, "((\(\d{3}\) ?)|
(\d{3}-))?\d{3}-\d{4}"))
        ModelState.AddModelError("Phone", "Invalid phone number.")
    End If
    If (contactToCreate.Email.Length > 0 AndAlso  Not Regex.IsMatch(contactToCreate.Email, "^[\w-\.]+@([\w-
]+\.)+[\w-]{2,4}$"))
        ModelState.AddModelError("Email", "Invalid email address.")
    End If
    If Not ModelState.IsValid Then
        Return View()
    End If

    ' Database logic
    Try
        _entities.AddToContactSet(contactToCreate)
        _entities.SaveChanges()
        Return RedirectToAction("Index")
    Catch
        Return View()
    End Try
End Function
```

The validate section enforces four distinct validation rules:

- The FirstName property must have a length greater than zero (and it cannot consist solely of spaces)
- The LastName property must have a length greater than zero (and it cannot consist solely of spaces)
- If the Phone property has a value (has a length greater than 0) then the Phone property must match a regular expression.
- If the Email property has a value (has a length greater than 0) then the Email property must match a regular expression.

When there is a validation rule violation, an error message is added to ModelState with the help of the AddModelError() method. When you add a message to ModelState, you provide the name of a property and the text of a validation error message. This error message is displayed in the view by the Html.ValidationSummary() and Html.ValidationMessage() helper methods.

After the validation rules are executed, the IsValid property of ModelState is checked. The IsValid property returns false when any validation error messages have been added to ModelState. If validation fails, the Create form is redisplayed with the error messages.

NOTE

I got the regular expressions for validating the phone number and email address from the regular expression repository at *http://regexlib.com*

Adding Validation Logic to the Edit Action

The Edit() action updates a Contact. The Edit() action needs to perform exactly the same validation as the Create() action. Instead of duplicating the same validation code, we should refactor the Contact controller so that both the Create() and Edit() actions call the same validation method.

The modified Contact controller class is contained in Listing 3. This class has a new ValidateContact() method that is called within both the Create() and Edit() actions.

Listing 3 - Controllers\ContactController.vb

```
Public Class ContactController
    Inherits System.Web.Mvc.Controller

    Private _entities As New ContactManagerDBEntities()

    Protected Sub ValidateContact(contactToValidate As Contact)
        If contactToValidate.FirstName.Trim().Length = 0 Then
            ModelState.AddModelError("FirstName", "First name is required.")
        End If
        If contactToValidate.LastName.Trim().Length = 0 Then
            ModelState.AddModelError("LastName", "Last name is required.")
        End If
        If (contactToValidate.Phone.Length > 0 AndAlso Not Regex.IsMatch(contactToValidate.Phone, "((\(\d{3}\)
?)|(\d{3}-))?\d{3}-\d{4}"))
            ModelState.AddModelError("Phone", "Invalid phone number.")
        End If
        If (contactToValidate.Email.Length > 0 AndAlso  Not Regex.IsMatch(contactToValidate.Email, "^[\w-
\.]+@([\w-]+\.)+[\w-]{2,4}$"))
            ModelState.AddModelError("Email", "Invalid email address.")
        End If
    End Sub

    '
    ' GET: /Contact

    Function Index() As ActionResult
        Return View(_entities.ContactSet.ToList())
    End Function

    '
    ' GET: /Contact/Create

    Function Create() As ActionResult
        Return View()
    End Function

    '
    ' POST: /Contact/Create

    <AcceptVerbs(HttpVerbs.Post)> _
    Function Create(<Bind(Exclude:="Id")> ByVal contactToCreate As Contact) As ActionResult
        ' Validation logic
        ValidateContact(contactToCreate)
        If Not ModelState.IsValid Then
            Return View()
        End If

        ' Database logic
```

```
        ' Database logic
        Try
            _entities.AddToContactSet(contactToCreate)
            _entities.SaveChanges()
            Return RedirectToAction("Index")
        Catch
            Return View()
        End Try
    End Function

    '
    ' GET: /Contact/Edit/5

    Function Edit(ByVal id As Integer) As ActionResult
        Dim contactToEdit = (from c in _entities.ContactSet _
                            where c.Id = id _
                            select c).FirstOrDefault()

        Return View(contactToEdit)
    End Function

    '
    ' POST: /Contact/Edit/5

    <AcceptVerbs(HttpVerbs.Post)> _
    Function Edit(ByVal contactToEdit As Contact) As ActionResult
        ' Validation logic
        ValidateContact(contactToEdit)
        If Not ModelState.IsValid Then
            Return View()
        End If

        ' Database logic
        Try
            Dim originalContact = (from c in _entities.ContactSet _
                                  where c.Id = contactToEdit.Id _
                                  select c).FirstOrDefault()
            _entities.ApplyPropertyChanges(originalContact.EntityKey.EntitySetName, contactToEdit)
            _entities.SaveChanges()
            Return RedirectToAction("Index")
        Catch
            Return View()
        End Try
    End Function

    '
    ' GET: /Contact/Delete/5

    Function Delete(ByVal id As Integer) As ActionResult
        Dim contactToDelete = (from c in _entities.ContactSet _
                            where c.Id = id _
                            select c).FirstOrDefault()

        Return View(contactToDelete)
    End Function

    '
    ' POST: /Contact/Delete/5

    <AcceptVerbs(HttpVerbs.Post)> _
    Function Delete(ByVal contactToDelete As Contact) As ActionResult
        Try
            Dim originalContact = (from c in _entities.ContactSet _
                                  where c.Id = contactToDelete.Id _
                                  select c).FirstOrDefault()
            _entities.DeleteObject(originalContact)
            _entities.SaveChanges()
            Return RedirectToAction("Index")
        Catch
            Return View()
```

```
            Return View()
        End Try
    End Function

End Class
```

Summary

In this iteration, we added basic form validation to our Contact Manager application. Our validation logic prevents users from submitting a new contact or editing an existing contact without supplying values for the FirstName and LastName properties. Furthermore, users must supply valid phone numbers and email addresses.

In this iteration, we added the validation logic to our Contact Manager application in the easiest way possible. However, mixing our validation logic into our controller logic will create problems for us in the long term. Our application will be more difficult to maintain and modify over time.

In the next iteration, we will refactor our validation logic and database access logic out of our controllers. We'll take advantage of several software design principles to enable us to create a more loosely coupled, and more maintainable, application.

> In this fourth iteration, we take advantage of several software design patterns to make it easier to maintain and modify the Contact Manager application. For example, we refactor our application to use the Repository pattern and the Dependency Injection pattern.

Building a Contact Management ASP.NET MVC Application (VB)

In this series of tutorials, we build an entire Contact Management application from start to finish. The Contact Manager application enables you to store contact information - names, phone numbers and email addresses - for a list of people.

We build the application over multiple iterations. With each iteration, we gradually improve the application. The goal of this multiple iteration approach is to enable you to understand the reason for each change.

- Iteration #1 - Create the application. In the first iteration, we create the Contact Manager in the simplest way possible. We add support for basic database operations: Create, Read, Update, and Delete (CRUD).
- Iteration #2 - Make the application look nice. In this iteration, we improve the appearance of the application by modifying the default ASP.NET MVC view master page and cascading style sheet.
- Iteration #3 - Add form validation. In the third iteration, we add basic form validation. We prevent people from submitting a form without completing required form fields. We also validate email addresses and phone numbers.
- Iteration #4 - Make the application loosely coupled. In this fourth iteration, we take advantage of several software design patterns to make it easier to maintain and modify the Contact Manager application. For example, we refactor our application to use the Repository pattern and the Dependency Injection pattern.
- Iteration #5 - Create unit tests. In the fifth iteration, we make our application easier to maintain and modify by adding unit tests. We mock our data model classes and build unit tests for our controllers and validation logic.
- Iteration #6 - Use test-driven development. In this sixth iteration, we add new functionality to our application by writing unit tests first and writing code against the unit tests. In this iteration, we add contact groups.
- Iteration #7 - Add Ajax functionality. In the seventh iteration, we improve the responsiveness and performance of our application by adding support for Ajax.

This Iteration

In this fourth iteration of the Contact Manager application, we refactor the application to make the application more loosely coupled. When an application is loosely coupled, you can modify the code in one part of the application without needing to modify the code in other parts of the application. Loosely coupled applications are more resilient to change.

Currently, all of the data access and validation logic used by the Contact Manager application is contained in the controller classes. This is a bad idea. Whenever you need to modify one part of your application, you risk introducing bugs into another part of your application. For example, if you modify your validation logic, you risk introducing new bugs into your data access or controller logic.

> **NOTE**
> (SRP), a class should never have more than one reason to change. Mixing controller, validation, and database logic is a massive violation of the Single Responsibility Principle.

There are several reasons that you might need to modify your application. You might need to add a new feature to your application, you might need to fix a bug in your application, or you might need to modify how a feature of your application is implemented. Applications are rarely static. They tend to grow and mutate over time.

Imagine, for example, that you decide to change how you implement your data access layer. Right now, the Contact Manager application uses the Microsoft Entity Framework to access the database. However, you might decide to migrate to a new or alternative data access technology such as ADO.NET Data Services or NHibernate. However, because the data access code is not isolated from the validation and controller code, there is no way to modify the data access code in your application without modifying other code that is not directly related to data access.

When an application is loosely coupled, on the other hand, you can make changes to one part of an application without touching other parts of an application. For example, you can switch data access technologies without modifying your validation or controller logic.

In this iteration, we take advantage of several software design patterns that enable us to refactor our Contact Manager application into a more loosely coupled application. When we are done, the Contact Manager won t do anything that it didn't do before. However, we'll be able to change the application more easily in the future.

> **NOTE**
> Refactoring is the process of rewriting an application in such a way that it does not lose any existing functionality.

Using the Repository Software Design Pattern

Our first change is to take advantage of a software design pattern called the Repository pattern. We'll use the Repository pattern to isolate our data access code from the rest of our application.

Implementing the Repository pattern requires us to complete the following two steps:

1. Create an interface
2. Create a concrete class that implements the interface

First, we need to create an interface that describes all of the data access methods that we need to perform. The IContactManagerRepository interface is contained in Listing 1. This interface describes five methods: CreateContact(), DeleteContact(), EditContact(), GetContact, and ListContacts().

Listing 1 - Models\IContactManagerRepository.vb

```
Public Interface IContactManagerRepository
Function CreateContact(ByVal contactToCreate As Contact) As Contact
Sub DeleteContact(ByVal contactToDelete As Contact)
Function EditContact(ByVal contactToUpdate As Contact) As Contact
Function GetContact(ByVal id As Integer) As Contact
Function ListContacts() As IEnumerable(Of Contact)
End Interface
```

Next, we need to create a concrete class that implements the IContactManagerRepository interface. Because we are using the Microsoft Entity Framework to access the database, we'll create a new class named EntityContactManagerRepository. This class is contained in Listing 2.

Listing 2 - Models\EntityContactManagerRepository.vb

```
Public Class EntityContactManagerRepository
Implements IContactManagerRepository

Private _entities As New ContactManagerDBEntities()

Public Function GetContact(ByVal id As Integer) As Contact Implements IContactManagerRepository.GetContact
    Return (From c In _entities.ContactSet _
            Where c.Id = id _
            Select c).FirstOrDefault()
End Function

Public Function ListContacts() As IEnumerable(Of Contact) Implements IContactManagerRepository.ListContacts
    Return _entities.ContactSet.ToList()
End Function

Public Function CreateContact(ByVal contactToCreate As Contact) As Contact Implements
IContactManagerRepository.CreateContact
    _entities.AddToContactSet(contactToCreate)
    _entities.SaveChanges()
    Return contactToCreate
End Function

Public Function EditContact(ByVal contactToEdit As Contact) As Contact Implements
IContactManagerRepository.EditContact
    Dim originalContact = GetContact(contactToEdit.Id)
    _entities.ApplyPropertyChanges(originalContact.EntityKey.EntitySetName, contactToEdit)
    _entities.SaveChanges()
    Return contactToEdit
End Function

Public Sub DeleteContact(ByVal contactToDelete As Contact) Implements IContactManagerRepository.DeleteContact
    Dim originalContact = GetContact(contactToDelete.Id)
    _entities.DeleteObject(originalContact)
    _entities.SaveChanges()
End Sub

End Class
```

Notice that the EntityContactManagerRepository class implements the IContactManagerRepository interface. The class implements all five of the methods described by that interface.

You might wonder why we need to bother with an interface. Why do we need to create both an interface and a class that implements it?

With one exception, the remainder of our application will interact with the interface and not the concrete class. Instead of calling the methods exposed by the EntityContactManagerRepository class, we'll call the methods exposed by the IContactManagerRepository interface.

That way, we can implement the interface with a new class without needing to modify the remainder of our application. For example, at some future date, we might want to implement an DataServicesContactManagerRepository class that implements the IContactManagerRepository interface. The DataServicesContactManagerRepository class might use ADO.NET Data Services to access a database instead of the Microsoft Entity Framework.

If our application code is programmed against the IContactManagerRepository interface instead of the concrete EntityContactManagerRepository class then we can switch concrete classes without modifying any of the rest of our code. For example, we can switch from the EntityContactManagerRepository class to the DataServicesContactManagerRepository class without modifying our data access or validation logic.

Programming against interfaces (abstractions) instead of concrete classes makes our application more resilient to change.

> **NOTE**
> You can quickly create an interface from a concrete class within Visual Studio by selecting the menu option Refactor, Extract Interface. For example, you can create the EntityContactManagerRepository class first and then use Extract Interface to generate the IContactManagerRepository interface automatically.

Using the Dependency Injection Software Design Pattern

Now that we have migrated our data access code to a separate Repository class, we need to modify our Contact controller to use this class. We will take advantage of a software design pattern called Dependency Injection to use the Repository class in our controller.

The modified Contact controller is contained in Listing 3.

Listing 3 - Controllers\ContactController.vb

```
Public Class ContactController
    Inherits System.Web.Mvc.Controller

    Private _repository As IContactManagerRepository

    Sub New()
        Me.New(new EntityContactManagerRepository())
    End Sub

    Sub New(repository As IContactManagerRepository)
        _repository = repository
    End Sub

    Protected Sub ValidateContact(contactToValidate As Contact)
        If contactToValidate.FirstName.Trim().Length = 0 Then
            ModelState.AddModelError("FirstName", "First name is required.")
        End If
        If contactToValidate.LastName.Trim().Length = 0 Then
            ModelState.AddModelError("LastName", "Last name is required.")
        End If
        If (contactToValidate.Phone.Length > 0 AndAlso Not Regex.IsMatch(contactToValidate.Phone, "((\(\d{3}\)
?)|(\d{3}-))?\d{3}-\d{4}"))
            ModelState.AddModelError("Phone", "Invalid phone number.")
        End If
        If (contactToValidate.Email.Length > 0 AndAlso  Not Regex.IsMatch(contactToValidate.Email, "^[\w-
\.]+@([\w-]+\.)+[\w-]{2,4}$"))
            ModelState.AddModelError("Email", "Invalid email address.")
        End If
    End Sub

    Function Index() As ActionResult
        Return View(_repository.ListContacts())
    End Function

    Function Create() As ActionResult
        Return View()
    End Function
```

```
    <AcceptVerbs(HttpVerbs.Post)> _
    Function Create(<Bind(Exclude:="Id")> ByVal contactToCreate As Contact) As ActionResult
        ' Validation logic
        ValidateContact(contactToCreate)
        If Not ModelState.IsValid Then
            Return View()
        End If

        ' Database logic
        Try
            _repository.CreateContact(contactToCreate)
            Return RedirectToAction("Index")
        Catch
            Return View()
        End Try
    End Function

    Function Edit(ByVal id As Integer) As ActionResult
        Return View(_repository.GetContact(id))
    End Function

    <AcceptVerbs(HttpVerbs.Post)> _
    Function Edit(ByVal contactToEdit As Contact) As ActionResult
        ' Validation logic
        ValidateContact(contactToEdit)
        If Not ModelState.IsValid Then
            Return View()
        End If

        ' Database logic
        Try
            _repository.EditContact(contactToEdit)
            Return RedirectToAction("Index")
        Catch
            Return View()
        End Try
    End Function

    Function Delete(ByVal id As Integer) As ActionResult
        Return View(_repository.GetContact(id))
    End Function

    <AcceptVerbs(HttpVerbs.Post)> _
    Function Delete(ByVal contactToDelete As Contact) As ActionResult
        Try
            _repository.DeleteContact(contactToDelete)
            Return RedirectToAction("Index")
        Catch
            Return View()
        End Try
    End Function

End Class
```

Notice that the Contact controller in Listing 3 has two constructors. The first constructor passes a concrete instance of the IContactManagerRepository interface to the second constructor. The Contact controller class uses *Constructor Dependency Injection*.

The one and only place that the EntityContactManagerRepository class is used is in the first constructor. The remainder of the class uses the IContactManagerRepository interface instead of the concrete EntityContactManagerRepository class.

This makes it easy to switch implementations of the IContactManagerRepository class in the future. If you want to use the DataServicesContactRepository class instead of the EntityContactManagerRepository class, just modify the first constructor.

Constructor Dependency injection also makes the Contact controller class very testable. In your unit tests, you can instantiate the Contact controller by passing a mock implementation of the IContactManagerRepository class. This feature of Dependency Injection will be very important to us in the next iteration when we build unit tests for the Contact Manager application.

> **NOTE**
>
> If you want to completely decouple the Contact controller class from a particular implementation of the IContactManagerRepository interface then you can take advantage of a framework that supports Dependency Injection such as StructureMap or the Microsoft Entity Framework (MEF). By taking advantage of a Dependency Injection framework, you never need to refer to a concrete class in your code.

Creating a Service Layer

You might have noticed that our validation logic is still mixed up with our controller logic in the modified controller class in Listing 3. For the same reason that it is a good idea to isolate our data access logic, it is a good idea to isolate our validation logic.

To fix this problem, we can create a separate service layer. The service layer is a separate layer that we can insert between our controller and repository classes. The service layer contains our business logic including all of our validation logic.

The ContactManagerService is contained in Listing 4. It contains the validation logic from the Contact controller class.

Listing 4 - Models\ContactManagerService.vb

```
Public Class ContactManagerService
Implements IContactManagerService

Private _validationDictionary As IValidationDictionary
Private _repository As IContactManagerRepository

Public Sub New(ByVal validationDictionary As IValidationDictionary)
    Me.New(validationDictionary, New EntityContactManagerRepository())
End Sub

Public Sub New(ByVal validationDictionary As IValidationDictionary, ByVal repository As
IContactManagerRepository)
    _validationDictionary = validationDictionary
    _repository = repository
End Sub

Public Function ValidateContact(ByVal contactToValidate As Contact) As Boolean
    If contactToValidate.FirstName.Trim().Length = 0 Then
        _validationDictionary.AddError("FirstName", "First name is required.")
    End If
    If contactToValidate.LastName.Trim().Length = 0 Then
        _validationDictionary.AddError("LastName", "Last name is required.")
    End If
    If contactToValidate.Phone.Length > 0 AndAlso (Not Regex.IsMatch(contactToValidate.Phone, "((\(\d{3}\) ?)|
(\d{3}-))?\d{3}-\d{4}")) Then
        _validationDictionary.AddError("Phone", "Invalid phone number.")
    End If
    If contactToValidate.Email.Length > 0 AndAlso (Not Regex.IsMatch(contactToValidate.Email, "^[\w-\.]+@([\w-
]+\.)+[\w-]{2,4}$")) Then
        _validationDictionary.AddError("Email", "Invalid email address.")
    End If
    Return _validationDictionary.IsValid
```

```
    Return _validationDictionary.IsValid
End Function

#Region "IContactManagerService Members"

Public Function CreateContact(ByVal contactToCreate As Contact) As Boolean Implements
IContactManagerService.CreateContact
    ' Validation logic
    If Not ValidateContact(contactToCreate) Then
        Return False
    End If

    ' Database logic
    Try
        _repository.CreateContact(contactToCreate)
    Catch
        Return False
    End Try
    Return True
End Function

Public Function EditContact(ByVal contactToEdit As Contact) As Boolean Implements
IContactManagerService.EditContact
    ' Validation logic
    If Not ValidateContact(contactToEdit) Then
        Return False
    End If

    ' Database logic
    Try
        _repository.EditContact(contactToEdit)
    Catch
        Return False
    End Try
    Return True
End Function

Public Function DeleteContact(ByVal contactToDelete As Contact) As Boolean Implements
IContactManagerService.DeleteContact
    Try
        _repository.DeleteContact(contactToDelete)
    Catch
        Return False
    End Try
    Return True
End Function

Public Function GetContact(ByVal id As Integer) As Contact Implements IContactManagerService.GetContact
    Return _repository.GetContact(id)
End Function

Public Function ListContacts() As IEnumerable(Of Contact) Implements IContactManagerService.ListContacts
    Return _repository.ListContacts()
End Function

#End Region
End Class
```

Notice that the constructor for the ContactManagerService requires a ValidationDictionary. The service layer communicates with the controller layer through this ValidationDictionary. We discuss the ValidationDictionary in detail in the following section when we discuss the Decorator pattern.

Notice, furthermore, that the ContactManagerService implements the IContactManagerService interface. You should always strive to program against interfaces instead of concrete classes. Other classes in the Contact Manager application do not interact with the ContactManagerService class directly. Instead, with one exception, the

remainder of the Contact Manager application is programmed against the IContactManagerService interface.

The IContactManagerService interface is contained in Listing 5.

Listing 5 - Models\IContactManagerService.vb

```
Public Interface IContactManagerService
Function CreateContact(ByVal contactToCreate As Contact) As Boolean
Function DeleteContact(ByVal contactToDelete As Contact) As Boolean
Function EditContact(ByVal contactToEdit As Contact) As Boolean
Function GetContact(ByVal id As Integer) As Contact
Function ListContacts() As IEnumerable(Of Contact)
End Interface
```

The modified Contact controller class is contained in Listing 6. Notice that the Contact controller no longer interacts with the ContactManager repository. Instead, the Contact controller interacts with the ContactManager service. Each layer is isolated as much as possible from other layers.

Listing 6 - Controllers\ContactController.vb

```
Public Class ContactController
    Inherits System.Web.Mvc.Controller

    Private _service As IContactManagerService

    Sub New()
        _service = new ContactManagerService(New ModelStateWrapper(ModelState))
    End Sub

    Sub New(service As IContactManagerService)
        _service = service
    End Sub

    Function Index() As ActionResult
        Return View(_service.ListContacts())
    End Function

    Function Create() As ActionResult
        Return View()
    End Function

    <AcceptVerbs(HttpVerbs.Post)> _
    Function Create(<Bind(Exclude:="Id")> ByVal contactToCreate As Contact) As ActionResult
        If _service.CreateContact(contactToCreate) Then
            Return RedirectToAction("Index")
        End If
        Return View()
    End Function

    Function Edit(ByVal id As Integer) As ActionResult
        Return View(_service.GetContact(id))
    End Function

    <AcceptVerbs(HttpVerbs.Post)> _
    Function Edit(ByVal contactToEdit As Contact) As ActionResult
        If _service.EditContact(contactToEdit) Then
            Return RedirectToAction("Index")
        End If
        Return View()
    End Function

    Function Delete(ByVal id As Integer) As ActionResult
        Return View(_service.GetContact(id))
    End Function

    <AcceptVerbs(HttpVerbs.Post)> _
    Function Delete(ByVal contactToDelete As Contact) As ActionResult
        If _service.DeleteContact(contactToDelete) Then
            return RedirectToAction("Index")
        End If
        Return View()
    End Function

End Class
```

Our application no longer runs afoul of the Single Responsibility Principle (SRP). The Contact controller in Listing 6 has been stripped of every responsibility other than controlling the flow of application execution. All the validation logic has been removed from the Contact controller and pushed into the service layer. All of the database logic has been pushed into the repository layer.

Using the Decorator Pattern

We want to be able to completely decouple our service layer from our controller layer. In principle, we should be able to compile our service layer in a separate assembly from our controller layer without needing to add a

reference to our MVC application.

However, our service layer needs to be able to pass validation error messages back to the controller layer. How can we enable the service layer to communicate validation error messages without coupling the controller and service layer? We can take advantage of a software design pattern named the Decorator pattern.

A controller uses a ModelStateDictionary named ModelState to represent validation errors. Therefore, you might be tempted to pass ModelState from the controller layer to the service layer. However, using ModelState in the service layer would make your service layer dependent on a feature of the ASP.NET MVC framework. This would be bad because, someday, you might want to use the service layer with a WPF application instead of an ASP.NET MVC application. In that case, you wouldn't want to reference the ASP.NET MVC framework to use the ModelStateDictionary class.

The Decorator pattern enables you to wrap an existing class in a new class in order to implement an interface. Our Contact Manager project includes the ModelStateWrapper class contained in Listing 7. The ModelStateWrapper class implements the interface in Listing 8.

Listing 7 - Models\Validation\ModelStateWrapper.vb

```
Public Class ModelStateWrapper
Implements IValidationDictionary

Private _modelState As ModelStateDictionary

Public Sub New(ByVal modelState As ModelStateDictionary)
    _modelState = modelState
End Sub

Public Sub AddError(ByVal key As String, ByVal errorMessage As String) Implements
IValidationDictionary.AddError
    _modelState.AddModelError(key, errorMessage)
End Sub

Public ReadOnly Property IsValid() As Boolean Implements IValidationDictionary.IsValid
    Get
        Return _modelState.IsValid
    End Get
End Property

End Class
```

Listing 8 - Models\Validation\IValidationDictionary.vb

```
Public Interface IValidationDictionary

Sub AddError(ByVal key As String, ByVal errorMessage As String)
ReadOnly Property IsValid() As Boolean

End Interface
```

If you take a close look at Listing 5 then you'll see that the ContactManager service layer uses the IValidationDictionary interface exclusively. The ContactManager service is not dependent on the ModelStateDictionary class. When the Contact controller creates the ContactManager service, the controller wraps its ModelState like this:

```
_service = new ContactManagerService(New ModelStateWrapper(ModelState))
```

Summary

In this iteration, we did not add any new functionality to the Contact Manager application. The goal of this iteration was to refactor the Contact Manager application so that is easier to maintain and modify.

First, we implemented the Repository software design pattern. We migrated all of the data access code to a separate ContactManager repository class.

We also isolated our validation logic from our controller logic. We created a separate service layer that contains all of our validation code. The controller layer interacts with the service layer, and the service layer interacts with the repository layer.

When we created the service layer, we took advantage of the Decorator pattern to isolate ModelState from our service layer. In our service layer, we programmed against the IValidationDictionary interface instead of ModelState.

Finally, we took advantage of a software design pattern named the Dependency Injection pattern. This pattern enables us to program against interfaces (abstractions) instead of concrete classes. Implementing the Dependency Injection design pattern also makes our code more testable. In the next iteration, we add unit tests to our project.

Iteration #5 – Create unit tests (VB)

by Microsoft

Download Code

> In the fifth iteration, we make our application easier to maintain and modify by adding unit tests. We mock our data model classes and build unit tests for our controllers and validation logic.

Building a Contact Management ASP.NET MVC Application (VB)

In this series of tutorials, we build an entire Contact Management application from start to finish. The Contact Manager application enables you to store contact information - names, phone numbers and email addresses - for a list of people.

We build the application over multiple iterations. With each iteration, we gradually improve the application. The goal of this multiple iteration approach is to enable you to understand the reason for each change.

- Iteration #1 - Create the application. In the first iteration, we create the Contact Manager in the simplest way possible. We add support for basic database operations: Create, Read, Update, and Delete (CRUD).
- Iteration #2 - Make the application look nice. In this iteration, we improve the appearance of the application by modifying the default ASP.NET MVC view master page and cascading style sheet.
- Iteration #3 - Add form validation. In the third iteration, we add basic form validation. We prevent people from submitting a form without completing required form fields. We also validate email addresses and phone numbers.
- Iteration #4 - Make the application loosely coupled. In this fourth iteration, we take advantage of several software design patterns to make it easier to maintain and modify the Contact Manager application. For example, we refactor our application to use the Repository pattern and the Dependency Injection pattern.
- Iteration #5 - Create unit tests. In the fifth iteration, we make our application easier to maintain and modify by adding unit tests. We mock our data model classes and build unit tests for our controllers and validation logic.
- Iteration #6 - Use test-driven development. In this sixth iteration, we add new functionality to our application by writing unit tests first and writing code against the unit tests. In this iteration, we add contact groups.
- Iteration #7 - Add Ajax functionality. In the seventh iteration, we improve the responsiveness and performance of our application by adding support for Ajax.

This Iteration

In the previous iteration of the Contact Manager application, we refactored the application to be more loosely coupled. We separated the application into distinct controller, service, and repository layers. Each layer interacts with the layer beneath it through interfaces.

We refactored the application to make the application easier to maintain and modify. For example, if we need to use a new data access technology, we can simply change the repository layer without touching the controller or service layer. By making the Contact Manager loosely coupled, we ve made the application more resilient to

change.

But, what happens when we need to add a new feature to the Contact Manager application? Or, what happens when we fix a bug? A sad, but well proven, truth of writing code is that whenever you touch code you create the risk of introducing new bugs.

For example, one fine day, your manager might ask you to add a new feature to the Contact Manager. She wants you to add support for Contact Groups. She wants you to enable users to organize their contacts into groups such as Friends, Business, and so on.

In order to implement this new feature, you'll need to modify all three layers of the Contact Manager application. You'll need to add new functionality to the controllers, the service layer, and the repository. As soon as you start modifying code, you risk breaking functionality that worked before.

Refactoring our application into separate layers, as we did in the previous iteration, was a good thing. It was a good thing because it enables us to make changes to entire layers without touching the rest of the application. However, if you want to make the code within a layer easier to maintain and modify, you need to create unit tests for the code.

You use a unit test to test an individual unit of code. These units of code are smaller than entire application layers. Typically, you use a unit test to verify whether a particular method in your code behaves in the way that you expect. For example, you would create a unit test for the CreateContact() method exposed by the ContactManagerService class.

The unit tests for an application work just like a safety net. Whenever you modify code in an application, you can run a set of unit tests to check whether the modification breaks existing functionality. Unit tests make your code safe to modify. Unit tests make all of the code in your application more resilient to change.

In this iteration, we add unit tests to our Contact Manager application. That way, in the next iteration, we can add Contact Groups to our application without worrying about breaking existing functionality.

> **NOTE**
> There are a variety of unit testing frameworks including NUnit, xUnit.net, and MbUnit. In this tutorial, we use the unit testing framework included with Visual Studio. However, you could just as easily use one of these alternative frameworks.

What Gets Tested

In the perfect world, all of your code would be covered by unit tests. In the perfect world, you would have the perfect safety net. You would be able to modify any line of code in your application and know instantly, by executing your unit tests, whether the change broke existing functionality.

However, we don t live in a perfect world. In practice, when writing unit tests, you concentrate on writing tests for your business logic (for example, validation logic). In particular, you *do not* write unit tests for your data access logic or your view logic.

To be useful, unit tests must execute very quickly. You easily can accumulate hundreds (or even thousands) of unit tests for an application. If the unit tests take a long time to run then you'll avoid executing them. In other words, long running unit tests are useless for day to day coding purposes.

For this reason, you typically do not write unit tests for code that interacts with a database. Running hundreds of unit tests against a live database would be too slow. Instead, you mock your database and write code that interacts with the mock database (we discuss mocking a database below).

For a similar reason, you typically do not write unit tests for views. In order to test a view, you must spin up a web server. Because spinning up a web server is a relatively slow process, creating unit tests for your views is not recommended.

If your view contains complicated logic then you should consider moving the logic into Helper methods. You can write unit tests for Helper methods that execute without spinning up a web server.

> **NOTE**
> While writing tests for data access logic or view logic is not a good idea when writing unit tests, these tests can be very valuable when building functional or integration tests.

> **NOTE**
> ASP.NET MVC is the Web Forms View Engine. While the Web Forms View Engine is dependent on a web server, other view engines might not be.

Using a Mock Object Framework

When building unit tests, you almost always need to take advantage of a Mock Object framework. A Mock Object framework enables you to create mocks and stubs for the classes in your application.

For example, you can use a Mock Object framework to generate a mock version of your repository class. That way, you can use the mock repository class instead of the real repository class in your unit tests. Using the mock repository enables you to avoid executing database code when executing a unit test.

Visual Studio does not include a Mock Object framework. However, there are several commercial and open source Mock Object frameworks available for the .NET framework:

1. Moq - This framework is available under the open source BSD license. You can download Moq from https://code.google.com/p/moq/.
2. Rhino Mocks - This framework is available under the open source BSD license. You can download Rhino Mocks from http://ayende.com/projects/rhino-mocks.aspx.
3. Typemock Isolator - This is a commercial framework. You can download a trial version from http://www.typemock.com/.

In this tutorial, I decided to use Moq. However, you could just as easily use Rhino Mocks or Typemock Isolator to create the Mock objects for the Contact Manager application.

Before you can use Moq, you need to complete the following steps:

1. .
2. Before you unzip the download, make sure that you right-click the file and click the button labeled **Unblock** (see Figure 1).
3. Unzip the download.
4. Add a reference to the Moq assembly to your Test project by selecting the menu option **Project, Add Reference** to open the **Add Reference** dialog. Under the Browse tab, browse to the folder where you unzipped Moq and select the Moq.dll assembly. Click the **OK** button (see Figure 2).

Figure 01: Unblocking Moq(Click to view full-size image)

Figure 02: References after adding Moq(Click to view full-size image)

Creating Unit Tests for the Service Layer

Let s start by creating a set of unit tests for our Contact Manager application s service layer. We'll use these tests to verify our validation logic.

Create a new folder named Models in the ContactManager.Tests project. Next, right-click the Models folder and select **Add, New Test**. The **Add New Test** dialog shown in Figure 3 appears. Select the **Unit Test** template and name your new test ContactManagerServiceTest.vb. Click the **OK** button to add your new test to your Test Project.

> **NOTE**
>
> In general, you want the folder structure of your Test Project to match the folder structure of your ASP.NET MVC project. For example, you place controller tests in a Controllers folder, model tests in a Models folder, and so on.

Figure 03: Models\ContactManagerServiceTest.cs(Click to view full-size image)

Initially, we want to test the CreateContact() method exposed by the ContactManagerService class. We'll create the following five tests:

- CreateContact() - Tests that CreateContact() returns the value true when a valid Contact is passed to the method.
- CreateContactRequiredFirstName() - Tests that an error message is added to model state when a Contact with a missing first name is passed to the CreateContact() method.
- CreateContactRequiredLastName() - Tests that an error message is added to model state when a Contact with a missing last name is passed to the CreateContact() method.
- CreateContactInvalidPhone() - Tests that an error message is added to model state when a Contact with an invalid phone number is passed to the CreateContact() method.
- CreateContactInvalidEmail() - Tests that an error message is added to model state when a Contact with an invalid email address is passed to the CreateContact() method..

The first test verifies that a valid Contact does not generate a validation error. The remaining tests check each of the validation rules.

The code for these tests is contained in Listing 1.

Listing 1 - Models\ContactManagerServiceTest.vb

```
Imports Microsoft.VisualStudio.TestTools.UnitTesting
Imports Moq
Imports System.Web.Mvc

<TestClass()> _
Public Class ContactManagerServiceTest

    Private _mockRepository As Mock(Of IContactManagerRepository)
    Private _modelState As ModelStateDictionary
    Private _service As IContactManagerService

    <TestInitialize()> _
    Public Sub Initialize()
        _mockRepository = New Mock(Of IContactManagerRepository)()
        _modelState = New ModelStateDictionary()
        _service = New ContactManagerService(new ModelStateWrapper(_modelState), _mockRepository.Object)
    End Sub

    <TestMethod()> _
    Public Sub CreateContact()
        ' Arrange
        Dim contactToCreate = Contact.CreateContact(-1, "Stephen", "Walther", "555-5555",
"steve@somewhere.com")

        ' Act
        Dim result = _service.CreateContact(contactToCreate)

        ' Assert
        Assert.IsTrue(result)
    End Sub

    <TestMethod()> _
    Public Sub CreateContactRequiredFirstName()
        ' Arrange
        Dim contactToCreate = Contact.CreateContact(-1, String.Empty, "Walther", "555-5555",
"steve@somewhere.com")

        ' Act
        Dim result = _service.CreateContact(contactToCreate)
```

```
        ' Assert
        Assert.IsFalse(result)
        Dim [error] = _modelState("FirstName").Errors(0)
        Assert.AreEqual("First name is required.", [error].ErrorMessage)
    End Sub

    <TestMethod()> _
    Public Sub CreateContactRequiredLastName()
        ' Arrange
        Dim contactToCreate = Contact.CreateContact(-1, "Stephen", String.Empty, "555-5555",
"steve@somewhere.com")

        ' Act
        Dim result = _service.CreateContact(contactToCreate)

        ' Assert
        Assert.IsFalse(result)
        Dim [error] = _modelState("LastName").Errors(0)
        Assert.AreEqual("Last name is required.", [error].ErrorMessage)
    End Sub

    <TestMethod()> _
    Public Sub CreateContactInvalidPhone()
        ' Arrange
        Dim contactToCreate = Contact.CreateContact(-1, "Stephen", "Walther", "apple", "steve@somewhere.com")

        ' Act
        Dim result = _service.CreateContact(contactToCreate)

        ' Assert
        Assert.IsFalse(result)
        Dim [error] = _modelState("Phone").Errors(0)
        Assert.AreEqual("Invalid phone number.", [error].ErrorMessage)
    End Sub

    <TestMethod()> _
    Public Sub CreateContactInvalidEmail()
        ' Arrange
        Dim contactToCreate = Contact.CreateContact(-1, "Stephen", "Walther", "555-5555", "apple")

        ' Act
        Dim result = _service.CreateContact(contactToCreate)

        ' Assert
        Assert.IsFalse(result)
        Dim [error] = _modelState("Email").Errors(0)
        Assert.AreEqual("Invalid email address.", [error].ErrorMessage)
    End Sub
End Class
```

Because we use the Contact class in Listing 1, we need to add a reference to the Microsoft Entity Framework to our Test project. Add a reference to the System.Data.Entity assembly.

Listing 1 contains a method named Initialize() that is decorated with the [TestInitialize] attribute. This method is called automatically before each of the unit tests is run (it is called 5 times right before each of the unit tests). The Initialize() method creates a mock repository with the following line of code:

```
_mockRepository = New Mock(Of IContactManagerRepository)()
```

This line of code uses the Moq framework to generate a mock repository from the IContactManagerRepository interface. The mock repository is used instead of the actual EntityContactManagerRepository to avoid accessing the database when each unit test is run. The mock repository implements the methods of the IContactManagerRepository interface, but the methods don t actually do anything.

> **NOTE**
> When using the Moq framework, there is a distinction between _mockRepository and _mockRepository.Object. The former refers to the Mock(Of IContactManagerRepository) class that contains methods for specifying how the mock repository will behave. The latter refers to the actual mock repository that implements the IContactManagerRepository interface.

The mock repository is used in the Initialize() method when creating an instance of the ContactManagerService class. All of the individual unit tests use this instance of the ContactManagerService class.

Listing 1 contains five methods that correspond to each of the unit tests. Each of these methods is decorated with the [TestMethod] attribute. When you run the unit tests, any method that has this attribute is called. In other words, any method that is decorated with the [TestMethod] attribute is a unit test.

The first unit test, named CreateContact(), verifies that calling CreateContact() returns the value true when a valid instance of the Contact class is passed to the method. The test creates an instance of the Contact class, calls the CreateContact() method, and verifies that CreateContact() returns the value true.

The remaining tests verify that when the CreateContact() method is called with an invalid Contact then the method returns false and the expected validation error message is added to model state. For example, the CreateContactRequiredFirstName() test creates an instance of the Contact class with an empty string for its FirstName property. Next, the CreateContact() method is called with the invalid Contact. Finally, the test verifies that CreateContact() returns false and that model state contains the expected validation error message "First name is required."

You can run the unit tests in Listing 1 by selecting the menu option **Test, Run, All Tests in Solution (CTRL+R, A)**. The results of the tests are displayed in the Test Results window (see Figure 4).

Figure 04: Test Results (Click to view full-size image)

Creating Unit Tests for Controllers

ASP.NET MVC application control the flow of user interaction. When testing a controller, you want to test whether the controller returns the right action result and view data. You also might want to test whether a controller interacts with model classes in the manner expected.

For example, Listing 2 contains two unit tests for the Contact controller Create() method. The first unit test verifies that when a valid Contact is passed to the Create() method then the Create() method redirects to the Index action. In other words, when passed a valid Contact, the Create() method should return a RedirectToRouteResult that represents the Index action.

We don t want to test the ContactManager service layer when we are testing the controller layer. Therefore, we mock the service layer with the following code in the Initialize method:

```
_service = New Mock(Of IContactManagerService)()
```

In the CreateValidContact() unit test, we mock the behavior of calling the service layer CreateContact() method with the following line of code:

```
_service.Expect( Function(s) s.CreateContact(contactToCreate) ).Returns(True)
```

This line of code causes the mock ContactManager service to return the value true when its CreateContact() method is called. By mocking the service layer, we can test the behavior of our controller without needing to execute any code in the service layer.

The second unit test verifies that the Create() action returns the Create view when an invalid contact is passed to the method. We cause the service layer CreateContact() method to return the value false with the following line of code:

```
_service.Expect( Function(s) s.CreateContact(contactToCreate) ).Returns(False)
```

If the Create() method behaves as we expect then it should return the Create view when the service layer returns the value false. That way, the controller can display the validation error messages in the Create view and the user has a chance to correct that invalid Contact properties.

If you plan to build unit tests for your controllers then you need to return explicit view names from your controller actions. For example, do not return a view like this:

Return View()

Instead, return the view like this:

Return View("Create")

If you are not explicit when returning a view then the ViewResult.ViewName property returns an empty string.

Listing 2 - Controllers\ContactControllerTest.vb

```
Imports Microsoft.VisualStudio.TestTools.UnitTesting
Imports Moq
Imports System.Web.Mvc

<TestClass()> _
Public Class ContactControllerTest

    Private _service As Mock(Of IContactManagerService)

    <TestInitialize()> _
    Public Sub Initialize()
        _service = New Mock(Of IContactManagerService)()
    End Sub

    <TestMethod()> _
    Public Sub CreateValidContact()
        ' Arrange
        Dim contactToCreate = New Contact()
        _service.Expect(Function(s) s.CreateContact(contactToCreate)).Returns(True)
        Dim controller = New ContactController(_service.Object)

        ' Act
        Dim result = CType(controller.Create(contactToCreate), RedirectToRouteResult)

        ' Assert
        Assert.AreEqual("Index", result.RouteValues("action"))
    End Sub

    <TestMethod()> _
    Public Sub CreateInvalidContact()
        ' Arrange
        Dim contactToCreate = New Contact()
        _service.Expect(Function(s) s.CreateContact(contactToCreate)).Returns(False)
        Dim controller = New ContactController(_service.Object)

        ' Act
        Dim result = CType(controller.Create(contactToCreate), ViewResult)

        ' Assert
        Assert.AreEqual("Create", result.ViewName)
    End Sub

End Class
```

Summary

In this iteration, we created unit tests for our Contact Manager application. We can run these unit tests at any time to verify that our application still behaves in the manner that we expect. The unit tests act as a safety net for our application enabling us to safely modify our application in the future.

We created two sets of unit tests. First, we tested our validation logic by creating unit tests for our service layer. Next, we tested our flow control logic by creating unit tests for our controller layer. When testing our service layer, we isolated our tests for our service layer from our repository layer by mocking our repository layer. When testing the controller layer, we isolated our tests for our controller layer by mocking the service layer.

In the next iteration, we modify the Contact Manager application so that it supports Contact Groups. We'll add this new functionality to our application using a software design process called test-driven development.

> In this sixth iteration, we add new functionality to our application by writing unit tests first and writing code against the unit tests. In this iteration, we add contact groups.

Building a Contact Management ASP.NET MVC Application (VB)

In this series of tutorials, we build an entire Contact Management application from start to finish. The Contact Manager application enables you to store contact information - names, phone numbers and email addresses - for a list of people.

We build the application over multiple iterations. With each iteration, we gradually improve the application. The goal of this multiple iteration approach is to enable you to understand the reason for each change.

- Iteration #1 - Create the application. In the first iteration, we create the Contact Manager in the simplest way possible. We add support for basic database operations: Create, Read, Update, and Delete (CRUD).
- Iteration #2 - Make the application look nice. In this iteration, we improve the appearance of the application by modifying the default ASP.NET MVC view master page and cascading style sheet.
- Iteration #3 - Add form validation. In the third iteration, we add basic form validation. We prevent people from submitting a form without completing required form fields. We also validate email addresses and phone numbers.
- Iteration #4 - Make the application loosely coupled. In this fourth iteration, we take advantage of several software design patterns to make it easier to maintain and modify the Contact Manager application. For example, we refactor our application to use the Repository pattern and the Dependency Injection pattern.
- Iteration #5 - Create unit tests. In the fifth iteration, we make our application easier to maintain and modify by adding unit tests. We mock our data model classes and build unit tests for our controllers and validation logic.
- Iteration #6 - Use test-driven development. In this sixth iteration, we add new functionality to our application by writing unit tests first and writing code against the unit tests. In this iteration, we add contact groups.
- Iteration #7 - Add Ajax functionality. In the seventh iteration, we improve the responsiveness and performance of our application by adding support for Ajax.

This Iteration

In the previous iteration of the Contact Manager application, we created unit tests to provide a safety net for our code. The motivation for creating the unit tests was to make our code more resilient to change. With unit tests in place, we can happily make any change to our code and immediately know whether we have broken existing functionality.

In this iteration, we use unit tests for an entirely different purpose. In this iteration, we use unit tests as part of an application design philosophy called *test-driven development*. When you practice test-driven development, you

write tests first and then write code against the tests.

More precisely, when practicing test-driven development, there are three steps that you complete when creating code (Red/ Green/Refactor):

1. Write a unit test that fails (Red)
2. Write code that passes the unit test (Green)
3. Refactor your code (Refactor)

First, you write the unit test. The unit test should express your intention for how you expect your code to behave. When you first create the unit test, the unit test should fail. The test should fail because you have not yet written any application code that satisfies the test.

Next, you write just enough code in order for the unit test to pass. The goal is to write the code in the laziest, sloppiest and fastest possible way. You should not waste time thinking about the architecture of your application. Instead, you should focus on writing the minimal amount of code necessary to satisfy the intention expressed by the unit test.

Finally, after you have written enough code, you can step back and consider the overall architecture of your application. In this step, you rewrite (refactor) your code by taking advantage of software design patterns -- such as the repository pattern -- so that your code is more maintainable. You can fearlessly rewrite your code in this step because your code is covered by unit tests.

There are many benefits that result from practicing test-driven development. First, test-driven development forces you to focus on code that actually needs to be written. Because you are constantly focused on just writing enough code to pass a particular test, you are prevented from wandering into the weeds and writing massive amounts of code that you will never use.

Second, a "test first" design methodology forces you to write code from the perspective of how your code will be used. In other words, when practicing test-driven development, you are constantly writing your tests from a user perspective. Therefore, test-driven development can result in cleaner and more understandable APIs.

Finally, test-driven development forces you to write unit tests as part of the normal process of writing an application. As a project deadline approaches, testing is typically the first thing that goes out the window. When practicing test-driven development, on the other hand, you are more likely to be virtuous about writing unit tests because test-driven development makes unit tests central to the process of building an application.

> **NOTE**
> To learn more about test-driven development, I recommend that you read Michael Feathers book **Working Effectively with Legacy Code**.

In this iteration, we add a new feature to our Contact Manager application. We add support for Contact Groups. You can use Contact Groups to organize your contacts into categories such as Business and Friend groups.

We'll add this new functionality to our application by following a process of test-driven development. We'll write our unit tests first and we'll write all of our code against these tests.

What Gets Tested

As we discussed in the previous iteration, you typically do not write unit tests for data access logic or view logic. You don t write unit tests for data access logic because accessing a database is a relatively slow operation. You don t write unit tests for view logic because accessing a view requires spinning up a web server which is a relatively slow operation. You shouldn't write a unit test unless the test can be executed over and over again very fast

Because test-driven development is driven by unit tests, we focus initially on writing controller and business logic.

We avoid touching the database or views. We won't modify the database or create our views until the very end of this tutorial. We start with what can be tested.

Creating User Stories

When practicing test-driven development, you always start by writing a test. This immediately raises the question: How do you decide what test to write first? To answer this question, you should write a set of *user stories*.

A user story is a very brief (usually one sentence) description of a software requirement. It should be a non-technical description of a requirement written from a user perspective.

Here s the set of user stories that describe the features required by the new Contact Group functionality:

1. User can view a list of contact groups.
2. User can create a new contact group.
3. User can delete an existing contact group.
4. User can select a contact group when creating a new contact.
5. User can select a contact group when editing an existing contact.
6. A list of contact groups is displayed in the Index view.
7. When a user clicks a contact group, a list of matching contacts is displayed.

Notice that this list of user stories is completely understandable by a customer. There is no mention of technical implementation details.

While in the process of building your application, the set of user stories can become more refined. You might break a user story into multiple stories (requirements). For example, you might decide that creating a new contact group should involve validation. Submitting a contact group without a name should return a validation error.

After you create a list of user stories, you are ready to write your first unit test. We'll start by creating a unit test for viewing the list of contact groups.

Listing Contact Groups

Our first user story is that a user should be able to view a list of contact groups. We need to express this story with a test.

Create a new unit test by right-clicking the Controllers folder in the ContactManager.Tests project, selecting **Add, New Test**, and selecting the **Unit Test** template (see Figure 1). Name the new unit test GroupControllerTest.vb and click the **OK** button.

Figure 01: Adding the GroupControllerTest unit test(Click to view full-size image)

Our first unit test is contained in Listing 1. This test verifies that the Index() method of the Group controller returns a set of Groups. The test verifies that a collection of Groups is returned in view data.

Listing 1 - Controllers\GroupControllerTest.vb

```
Imports Microsoft.VisualStudio.TestTools.UnitTesting
Imports System.Web.Mvc

<TestClass()> _
Public Class GroupControllerTest

    <TestMethod()> _
    Public Sub Index()
        ' Arrange
        Dim controller = New GroupController()

        ' Act
        Dim result = CType(controller.Index(), ViewResult)

        ' Assert
        Assert.IsInstanceOfType(result.ViewData.Model, GetType(IEnumerable(Of Group)))
    End Sub
End Class
```

When you first type the code in Listing 1 in Visual Studio, you'll get a lot of red squiggly lines. We have not created the GroupController or Group classes.

At this point, we can t even build our application so we can t execute our first unit test. That s good. That counts as a failing test. Therefore, we now have permission to start writing application code. We need to write enough code to execute our test.

The Group controller class in Listing 2 contains the bare minimum of code required to pass the unit test. The Index() action returns a statically coded list of Groups (the Group class is defined in Listing 3).

Listing 2 - Controllers\GroupController.vb

```
Public Class GroupController
    Inherits System.Web.Mvc.Controller

    Function Index() As ActionResult
        Dim groups = new List(Of Group)
        Return View(groups)
    End Function

End Class
```

Listing 3 - Models\Group.vb

```
Public Class Group

End Class
```

After we add the GroupController and Group classes to our project, our first unit test completes successfully (see Figure 2). We have done the minimum work required to pass the test. It is time to celebrate.

Figure 02: Success!(Click to view full-size image)

Creating Contact Groups

Now we can move on to the second user story. We need to be able to create new contact groups. We need to express this intention with a test.

The test in Listing 4 verifies that calling the Create() method with a new Group adds the Group to the list of Groups returned by the Index() method. In other words, if I create a new group then I should be able to get the new Group back from the list of Groups returned by the Index() method.

Listing 4 - Controllers\GroupControllerTest.vb

```
<TestMethod> _
Public Sub Create()
    ' Arrange
    Dim controller = New GroupController()

    ' Act
    Dim groupToCreate = New Group()
    controller.Create(groupToCreate)

    ' Assert
    Dim result = CType(controller.Index(), ViewResult)
    Dim groups = CType(result.ViewData.Model, IEnumerable(Of Group))
    CollectionAssert.Contains(groups.ToList(), groupToCreate)
End Sub
```

The test in Listing 4 calls the Group controller Create() method with a new contact Group. Next, the test verifies that calling the Group controller Index() method returns the new Group in view data.

The modified Group controller in Listing 5 contains the bare minimum of changes required to pass the new test.

Listing 5 - Controllers\GroupController.vb

```
Public Class GroupController
Inherits Controller

Private _groups As IList(Of Group) = New List(Of Group)()

Public Function Index() As ActionResult
    Return View(_groups)
End Function

Public Function Create(ByVal groupToCreate As Group) As ActionResult
    _groups.Add(groupToCreate)
    Return RedirectToAction("Index")

End Function
End Class
```

The Group controller in Listing 5 has a new Create() action. This action adds a Group to a collection of Groups. Notice that the Index() action has been modified to return the contents of the collection of Groups.

Once again, we have performed the bare minimum amount of work required to pass the unit test. After we make these changes to the Group controller, all of our unit tests pass.

Adding Validation

This requirement was not stated explicitly in the user story. However, it is reasonable to require that a Group have a name. Otherwise, organizing contacts into Groups would not be very useful.

Listing 6 contains a new test that expresses this intention. This test verifies that attempting to create a Group without supplying a name results in a validation error message in model state.

Listing 6 - Controllers\GroupControllerTest.vb

```
<TestMethod> _
Public Sub CreateRequiredName()
    ' Arrange
    Dim controller = New GroupController()

    ' Act
    Dim groupToCreate As New Group()
    groupToCreate.Name = String.Empty
    Dim result = CType(controller.Create(groupToCreate), ViewResult)

    ' Assert
    Dim [error] = result.ViewData.ModelState("Name").Errors(0)
    Assert.AreEqual("Name is required.", [error].ErrorMessage)
End Sub
```

In order to satisfy this test, we need to add a Name property to our Group class (see Listing 7). Furthermore, we need to add a tiny bit of validation logic to our Group controller s Create() action (see Listing 8).

Listing 7 - Models\Group.vb

```
Public Class Group

    Private _name As String

    Public Property Name() As String
    Get
        Return _name
    End Get
    Set(ByVal value As String)
        _name = value
    End Set
End Property

End Class
```

Listing 8 - Controllers\GroupController.vb

```
Public Function Create(ByVal groupToCreate As Group) As ActionResult
    ' Validation logic
    If groupToCreate.Name.Trim().Length = 0 Then
    ModelState.AddModelError("Name", "Name is required.")
    Return View("Create")
    End If

    ' Database logic
    _groups.Add(groupToCreate)
    Return RedirectToAction("Index")
End Function
```

Notice that the Group controller Create() action now contains both validation and database logic. Currently, the database used by the Group controller consists of nothing more than an in-memory collection.

Time to Refactor

The third step in Red/Green/Refactor is the Refactor part. At this point, we need to step back from our code and consider how we can refactor our application to improve its design. The Refactor stage is the stage at which we think hard about the best way of implementing software design principles and patterns.

We are free to modify our code in any way that we choose to improve the design of the code. We have a safety net of unit tests that prevent us from breaking existing functionality.

Right now, our Group controller is a mess from the perspective of good software design. The Group controller contains a tangled mess of validation and data access code. To avoid violating the Single Responsibility Principle, we need to separate these concerns into different classes.

Our refactored Group controller class is contained in Listing 9. The controller has been modified to use the ContactManager service layer. This is the same service layer that we use with the Contact controller.

Listing 10 contains the new methods added to the ContactManager service layer to support validating, listing, and creating groups. The IContactManagerService interface was updated to include the new methods.

Listing 11 contains a new FakeContactManagerRepository class that implements the IContactManagerRepository interface. Unlike the EntityContactManagerRepository class that also implements the IContactManagerRepository interface, our new FakeContactManagerRepository class does not communicate with the database. The FakeContactManagerRepository class uses an in-memory collection as a proxy for the database. We'll use this class in our unit tests as a fake repository layer.

Listing 9 - Controllers\GroupController.vb

```
Public Class GroupController
Inherits Controller

Private _service As IContactManagerService

Public Sub New()
    _service = New ContactManagerService(New ModelStateWrapper(Me.ModelState))

End Sub

Public Sub New(ByVal service As IContactManagerService)
    _service = service
End Sub

Public Function Index() As ActionResult
    Return View(_service.ListGroups())
End Function

Public Function Create(ByVal groupToCreate As Group) As ActionResult
    If _service.CreateGroup(groupToCreate) Then
        Return RedirectToAction("Index")
    End If
    Return View("Create")
End Function

End Class
```

Listing 10 - Controllers\ContactManagerService.vb

```
Public Function ValidateGroup(ByVal groupToValidate As Group) As Boolean
If groupToValidate.Name.Trim().Length = 0 Then
    _validationDictionary.AddError("Name", "Name is required.")
End If
Return _validationDictionary.IsValid
End Function

Public Function CreateGroup(ByVal groupToCreate As Group) As Boolean Implements
IContactManagerService.CreateGroup
    ' Validation logic
    If Not ValidateGroup(groupToCreate) Then
        Return False
    End If

    ' Database logic
    Try
        _repository.CreateGroup(groupToCreate)
    Catch
        Return False
    End Try
    Return True
End Function

Public Function ListGroups() As IEnumerable(Of Group) Implements IContactManagerService.ListGroups
    Return _repository.ListGroups()
End Function
```

Listing 11 - Controllers\FakeContactManagerRepository.vb

```
Public Class FakeContactManagerRepository
Implements IContactManagerRepository

Private _groups As IList(Of Group) = New List(Of Group)()

#Region "IContactManagerRepository Members"

' Group methods

Public Function CreateGroup(ByVal groupToCreate As Group) As Group Implements
IContactManagerRepository.CreateGroup
    _groups.Add(groupToCreate)
    Return groupToCreate
End Function

Public Function ListGroups() As IEnumerable(Of Group) Implements IContactManagerRepository.ListGroups
    Return _groups
End Function

' Contact methods

Public Function CreateContact(ByVal contactToCreate As Contact) As Contact Implements
IContactManagerRepository.CreateContact
    Throw New NotImplementedException()
End Function

Public Sub DeleteContact(ByVal contactToDelete As Contact) Implements IContactManagerRepository.DeleteContact
    Throw New NotImplementedException()
End Sub

Public Function EditContact(ByVal contactToEdit As Contact) As Contact Implements
IContactManagerRepository.EditContact
    Throw New NotImplementedException()
End Function

Public Function GetContact(ByVal id As Integer) As Contact Implements IContactManagerRepository.GetContact
    Throw New NotImplementedException()
End Function

Public Function ListContacts() As IEnumerable(Of Contact) Implements IContactManagerRepository.ListContacts
    Throw New NotImplementedException()
End Function

#End Region
End Class
```

Modifying the IContactManagerRepository interface requires use to implement the CreateGroup() and ListGroups() methods in the EntityContactManagerRepository class. The laziest and fastest way to do this is to add stub methods that look like this:

```
Public Function CreateGroup(groupToCreate As Group) As Group Implements IContactManagerRepository.CreateGroup

    throw New NotImplementedException()

End Function

Public Function ListGroups() As IEnumerable(Of Group) Implements IContactManagerRepository.ListGroups

    throw New NotImplementedException()

End Function
```

Finally, these changes to the design of our application require us to make some modifications to our unit tests. We now need to use the FakeContactManagerRepository when performing the unit tests. The updated

GroupControllerTest class is contained in Listing 12.

Listing 12 - Controllers\GroupControllerTest.vb

```
Imports Microsoft.VisualStudio.TestTools.UnitTesting
Imports System.Web.Mvc

<TestClass()> _
Public Class GroupControllerTest

    Private _repository As IContactManagerRepository
    Private _modelState As ModelStateDictionary
    Private _service As IContactManagerService

    <TestInitialize()> _
    Public Sub Initialize()
        _repository = New FakeContactManagerRepository()
        _modelState = New ModelStateDictionary()
        _service = New ContactManagerService(New ModelStateWrapper(_modelState), _repository)
    End Sub

    <TestMethod()> _
    Public Sub Index()
        ' Arrange
        Dim controller = New GroupController(_service)

        ' Act
        Dim result = CType(controller.Index(), ViewResult)

        ' Assert
        Assert.IsInstanceOfType(result.ViewData.Model, GetType(IEnumerable(Of Group)))
    End Sub

    <TestMethod()> _
    Public Sub Create()
        ' Arrange
        Dim controller = New GroupController(_service)

        ' Act
        Dim groupToCreate = New Group()
        groupToCreate.Name = "Business"
        controller.Create(groupToCreate)

        ' Assert
        Dim result = CType(controller.Index(), ViewResult)
        Dim groups = CType(result.ViewData.Model, IEnumerable(Of Group))
        CollectionAssert.Contains(groups.ToList(), groupToCreate)
    End Sub

    <TestMethod()> _
    Public Sub CreateRequiredName()
        ' Arrange
        Dim controller = New GroupController(_service)

        ' Act
        Dim groupToCreate = New Group()
        groupToCreate.Name = String.Empty
        Dim result = CType(controller.Create(groupToCreate), ViewResult)

        ' Assert
        Dim nameError = _modelState("Name").Errors(0)
        Assert.AreEqual("Name is required.", nameError.ErrorMessage)
    End Sub

End Class
```

After we make all of these changes, once again, all of our unit tests pass. We have completed the entire cycle of Red/Green/Refactor. We have implemented the first two user stories. We now have supporting unit tests for the requirements expressed in the user stories. Implementing the remainder of the user stories involves repeating the same cycle of Red/Green/Refactor.

Modifying our Database

Unfortunately, even though we have satisfied all of the requirements expressed by our unit tests, our work is not done. We still need to modify our database.

We need to create a new Group database table. Follow these steps:

1. In the Server Explorer window, right-click the Tables folder and select the menu option **Add New Table**.
2. Enter the two columns described below in the Table Designer.
3. Mark the Id column as a primary key and Identity column.
4. Save the new table with the name Groups by clicking the icon of the floppy.

COLUMN NAME	DATA TYPE	ALLOW NULLS
Id	int	False
Name	nvarchar(50)	False

Next, we need to delete all of the data from the Contacts table (otherwise, we won't be able to create a relationship between the Contacts and Groups tables). Follow these steps:

1. Right-click the Contacts table and select the menu option **Show Table Data**.
2. Delete all of the rows.

Next, we need to define a relationship between the Groups database table and the existing Contacts database table. Follow these steps:

1. Double-click the Contacts table in the Server Explorer window to open the Table Designer.
2. Add a new integer column to the Contacts table named GroupId.
3. Click the Relationship button to open the Foreign Key Relationships dialog (see Figure 3).
4. Click the Add button.
5. Click the ellipsis button that appears next to the Table and Columns Specification button.
6. In the Tables and Columns dialog, select Groups as the primary key table and Id as the primary key column. Select Contacts as the foreign key table and GroupId as the foreign key column (see Figure 4). Click the OK button.
7. Under **INSERT and UPDATE Specification**, select the value **Cascade** for **Delete Rule**.
8. Click the Close button to close the Foreign Key Relationships dialog.
9. Click the Save button to save the changes to the Contacts table.

Figure 03: Creating a database table relationship (Click to view full-size image)

Figure 04: Specifying table relationships(Click to view full-size image)

Updating our Data Model

Next, we need to update our data model to represent the new database table. Follow these steps:

1. Double-click the ContactManagerModel.edmx file in the Models folder to open the Entity Designer.
2. Right-click the Designer surface and select the menu option **Update Model from Database**.
3. In the Update Wizard, select the Groups table and click the Finish button (see Figure 5).
4. Right-click the Groups entity and select the menu option **Rename**. Change the name of the *Groups* entity to *Group* (singular).
5. Right-click the Groups navigation property that appears at the bottom of the Contact entity. Change the name of the *Groups* navigation property to *Group* (singular).

Figure 05: Updating an Entity Framework model from the database(Click to view full-size image)

After you complete these steps, your data model will represent both the Contacts and Groups tables. The Entity Designer should show both entities (see Figure 6).

Figure 06: Entity Designer displaying Group and Contact(Click to view full-size image)

Creating our Repository Classes

Next, we need to implement our repository class. Over the course of this iteration, we added several new methods to the IContactManagerRepository interface while writing code to satisfy our unit tests. The final version of the IContactManagerRepository interface is contained in Listing 14.

Listing 14 - Models\IContactManagerRepository.vb

```
Public Interface IContactManagerRepository
' Contact methods
Function CreateContact(ByVal groupId As Integer, ByVal contactToCreate As Contact) As Contact
Sub DeleteContact(ByVal contactToDelete As Contact)
Function EditContact(ByVal groupId As Integer, ByVal contactToEdit As Contact) As Contact
Function GetContact(ByVal id As Integer) As Contact

' Group methods
Function CreateGroup(ByVal groupToCreate As Group) As Group
Function ListGroups() As IEnumerable(Of Group)
Function GetGroup(ByVal groupId As Integer) As Group
Function GetFirstGroup() As Group
Sub DeleteGroup(ByVal groupToDelete As Group)

End Interface
```

We haven't actually implemented any of the methods related to working with contact groups in our real EntityContactManagerRepository class. Currently, the EntityContactManagerRepository class has stub methods for each of the contact group methods listed in the IContactManagerRepository interface. For example, the ListGroups() method currently looks like this:

```
Public Function ListGroups() As IEnumerable(Of Group) Implements IContactManagerRepository.ListGroups

    throw New NotImplementedException()

End Function
```

The stub methods enabled us to compile our application and pass the unit tests. However, now it is time to actually implement these methods. The final version of the EntityContactManagerRepository class is contained in Listing 13.

Listing 13 - Models\EntityContactManagerRepository.vb

```
Public Class EntityContactManagerRepository
Implements IContactManagerRepository

Private _entities As New ContactManagerDBEntities()

' Contact methods

Public Function GetContact(ByVal id As Integer) As Contact Implements IContactManagerRepository.GetContact
    Return (From c In _entities.ContactSet.Include("Group") _
            Where c.Id = id _
            Select c).FirstOrDefault()
End Function

Public Function CreateContact(ByVal groupId As Integer, ByVal contactToCreate As Contact) As Contact
Implements IContactManagerRepository.CreateContact
    ' Associate group with contact
    contactToCreate.Group = GetGroup(groupId)

    ' Save new contact
    _entities.AddToContactSet(contactToCreate)
    _entities.SaveChanges()
    Return contactToCreate
End Function

Public Function EditContact(ByVal groupId As Integer, ByVal contactToEdit As Contact) As Contact Implements
IContactManagerRepository.EditContact
    ' Get original contact
    Dim originalContact = GetContact(contactToEdit.Id)

    ' Update with new group
    originalContact.Group = GetGroup(groupId)

    ' Save changes
    _entities.ApplyPropertyChanges(originalContact.EntityKey.EntitySetName, contactToEdit)
    _entities.SaveChanges()
    Return contactToEdit
End Function

Public Sub DeleteContact(ByVal contactToDelete As Contact) Implements IContactManagerRepository.DeleteContact
    Dim originalContact = GetContact(contactToDelete.Id)
    _entities.DeleteObject(originalContact)
    _entities.SaveChanges()
End Sub

    ' Group methods

Public Function CreateGroup(ByVal groupToCreate As Group) As Group Implements
IContactManagerRepository.CreateGroup
    _entities.AddToGroupSet(groupToCreate)
    _entities.SaveChanges()
    Return groupToCreate
End Function

Public Function ListGroups() As IEnumerable(Of Group) Implements IContactManagerRepository.ListGroups
    Return _entities.GroupSet.ToList()
End Function

Public Function GetFirstGroup() As Group Implements IContactManagerRepository.GetFirstGroup
    Return _entities.GroupSet.Include("Contacts").FirstOrDefault()
End Function

Public Function GetGroup(ByVal id As Integer) As Group Implements IContactManagerRepository.GetGroup
    Return (From g In _entities.GroupSet.Include("Contacts") _
            Where g.Id = id _
            Select g).FirstOrDefault()
End Function
```

```
Public Sub DeleteGroup(ByVal groupToDelete As Group) Implements IContactManagerRepository.DeleteGroup
    Dim originalGroup = GetGroup(groupToDelete.Id)
    _entities.DeleteObject(originalGroup)
    _entities.SaveChanges()
End Sub

End Class
```

Creating the Views

ASP.NET MVC application when you use the default ASP.NET view engine. So, you don t create views in response to a particular unit test. However, because an application would be useless without views, we can t complete this iteration without creating and modifying the views contained in the Contact Manager application.

We need to create the following new views for managing contact groups (see Figure 7):

- Views\Group\Index.aspx - Displays list of contact groups
- Views\Group\Delete.aspx - Displays confirmation form for deleting a contact group

Figure 07: The Group Index view(Click to view full-size image)

We need to modify the following existing views so that they include contact groups:

- Views\Home\Create.aspx
- Views\Home\Edit.aspx
- Views\Home\Index.aspx

You can see the modified views by looking at the Visual Studio application that accompanies this tutorial. For example, Figure 8 illustrates the Contact Index view.

Figure 08: The Contact Index view(Click to view full-size image)

Summary

In this iteration, we added new functionality to our Contact Manager application by following a test-driven development application design methodology. We started by creating a set of user stories. We created a set of unit tests that corresponds to the requirements expressed by the user stories. Finally, we wrote just enough code to satisfy the requirements expressed by the unit tests.

After we finished writing enough code to satisfy the requirements expressed by the unit tests, we updated our database and views. We added a new Groups table to our database and updated our Entity Framework Data Model. We also created and modified a set of views.

In the next iteration -- the final iteration -- we rewrite our application to take advantage of Ajax. By taking advantage of Ajax, we'll improve the responsiveness and performance of the Contact Manager application.

> In the seventh iteration, we improve the responsiveness and performance of our application by adding support for Ajax.

Building a Contact Management ASP.NET MVC Application (VB)

In this series of tutorials, we build an entire Contact Management application from start to finish. The Contact Manager application enables you to store contact information - names, phone numbers and email addresses - for a list of people.

We build the application over multiple iterations. With each iteration, we gradually improve the application. The goal of this multiple iteration approach is to enable you to understand the reason for each change.

- Iteration #1 - Create the application. In the first iteration, we create the Contact Manager in the simplest way possible. We add support for basic database operations: Create, Read, Update, and Delete (CRUD).
- Iteration #2 - Make the application look nice. In this iteration, we improve the appearance of the application by modifying the default ASP.NET MVC view master page and cascading style sheet.
- Iteration #3 - Add form validation. In the third iteration, we add basic form validation. We prevent people from submitting a form without completing required form fields. We also validate email addresses and phone numbers.
- Iteration #4 - Make the application loosely coupled. In this fourth iteration, we take advantage of several software design patterns to make it easier to maintain and modify the Contact Manager application. For example, we refactor our application to use the Repository pattern and the Dependency Injection pattern.
- Iteration #5 - Create unit tests. In the fifth iteration, we make our application easier to maintain and modify by adding unit tests. We mock our data model classes and build unit tests for our controllers and validation logic.
- Iteration #6 - Use test-driven development. In this sixth iteration, we add new functionality to our application by writing unit tests first and writing code against the unit tests. In this iteration, we add contact groups.
- Iteration #7 - Add Ajax functionality. In the seventh iteration, we improve the responsiveness and performance of our application by adding support for Ajax.

This Iteration

In this iteration of the Contact Manager application, we refactor our application to make use of Ajax. By taking advantage of Ajax, we make our application more responsive. We can avoid rendering an entire page when we need to update only a certain region in a page.

We'll refactor our Index view so that we don t need to redisplay the entire page whenever someone selects a new contact group. Instead, when someone clicks a contact group, we'll just update the list of contacts and leave the rest of the page alone.

We'll also change the way our delete link works. Instead of displaying a separate confirmation page, we'll display a JavaScript confirmation dialog. If you confirm that you want to delete a contact, an HTTP DELETE operation is performed against the server to delete the contact record from the database.

Furthermore, we will take advantage of jQuery to add animation effects to our Index view. We'll display an animation when the new list of contacts is being fetched from the server.

Finally, we'll take advantage of the ASP.NET AJAX framework support for managing browser history. We'll create history points whenever we perform an Ajax call to update the contact list. That way, the browser backward and forward buttons will work.

Why use Ajax?

Using Ajax has many benefits. First, adding Ajax functionality to an application results in a better user experience. In a normal web application, the entire page must be posted back to the server each and every time a user performs an action. Whenever you perform an action, the browser locks and the user must wait until the entire page is fetched and redisplayed.

This would be an unacceptable experience in the case of a desktop application. But, traditionally, we lived with this bad user experience in the case of a web application because we did not know that we could do any better. We thought it was a limitation of web applications when, in actuality, it was just a limitation of our imaginations.

In an Ajax application, you don t need to bring the user experience to a halt just to update a page. Instead, you can perform an asynchronous request in the background to update the page. You don t force the user to wait while part of the page gets updated.

By taking advantage of Ajax, you also can improve the performance of your application. Consider how the Contact Manager application works right now without Ajax functionality. When you click a contact group, the entire Index view must be redisplayed. The list of contacts and list of contact groups must be retrieved from the database server. All of this data must be passed across the wire from web server to web browser.

After we add Ajax functionality to our application, however, we can avoid redisplaying the entire page when a user clicks a contact group. We no longer need to grab the contact groups from the database. We also don t need to push the entire Index view across the wire. By taking advantage of Ajax, we reduce the amount of work that our database server must perform and we reduce the amount of network traffic required by our application.

Don t be Afraid of Ajax

Some developers avoid using Ajax because they worry about downlevel browsers. They want to make sure that their web applications will still work when accessed by a browser that does not support JavaScript. Because Ajax depends on JavaScript, some developers avoid using Ajax.

However, if you are careful about how you implement Ajax then you can build applications that work with both uplevel and downlevel browsers. Our Contact Manager application will work with browsers that support JavaScript and browsers that do not.

If you use the Contact Manager application with a browser that supports JavaScript then you will have a better user experience. For example, when you click a contact group, only the region of the page that displays contacts will be updated.

If, on the other hand, you use the Contact Manager application with a browser that does not support JavaScript (or that has JavaScript disabled) then you will have a slightly less desirable user experience. For example, when you click a contact group, the entire Index view must be posted back to the browser in order to display the matching list of contacts.

Adding the Required JavaScript Files

We'll need to use three JavaScript files to add Ajax functionality to our application. All three of these files are included in the Scripts folder of a new ASP.NET MVC application.

If you plan to use Ajax in multiple pages in your application then it makes sense to include the required JavaScript files in your application s view master page. That way, the JavaScript files will be included in all of the pages in your application automatically.

Add the following JavaScript includes inside the <head> tag of your view master page:

```
<script src="../../Scripts/MicrosoftAjax.js" type="text/javascript"></script>
    <script src="../../Scripts/MicrosoftMvcAjax.js" type="text/javascript"></script>
    <script src="../../Scripts/jquery-1.2.6.min.js" type="text/javascript"></script>
```

Refactoring the Index View to use Ajax

Let s start by modifying our Index view so that clicking a contact group only updates the region of the view that displays contacts. The red box in Figure 1 contains the region that we want to update.

Figure 01: Updating only contacts(Click to view full-size image)

The first step is to separate the part of the view that we want to update asynchronously into a separate partial (view user control). The section of the Index view that displays the table of contacts has been moved into the partial in Listing 1.

Listing 1 - Views\Contact\ContactList.ascx

```
<%@ Control Language="VB" Inherits="System.Web.Mvc.ViewUserControl(Of ContactManager.Group)" %>
<table class="data-table" cellpadding="0" cellspacing="0">
    <thead>
        <tr>
            <th class="actions edit">
                Edit
            </th>
            <th class="actions delete">
                Delete
            </th>
            <th>
                Name
            </th>
            <th>
                Phone
            </th>
            <th>
                Email
            </th>
        </tr>
    </thead>
    <tbody>
        <% For Each item in Model.Contacts %>
        <tr>
            <td class="actions edit">
                <a href='<%= Url.Action("Edit", New With {.id=item.Id}) %>'><img src="../../Content/Edit.png"
alt="Edit" /></a>
            </td>
            <td class="actions delete">
                <a href='<%= Url.Action("Delete", New With {.id=item.Id}) %>'><img
src="../../Content/Delete.png" alt="Delete" /></a>
            </td>
            <th>
                <%= Html.Encode(item.FirstName) %>
                <%= Html.Encode(item.LastName) %>
            </th>
            <td>
                <%= Html.Encode(item.Phone) %>
            </td>
            <td>
                <%= Html.Encode(item.Email) %>
            </td>
        </tr>
        <% Next %>
    </tbody>
</table>
```

Notice that the partial in Listing 1 has a different model than the Index view. The *Inherits* attribute in the <%@ Page %> directive specifies that the partial inherits from the ViewUserControl<Group> class.

The updated Index view is contained in Listing 2.

Listing 2 - Views\Contact\Index.aspx

```
<%@ Page Title="" Language="VB" MasterPageFile="~/Views/Shared/Site.Master"
Inherits="System.Web.Mvc.ViewPage(Of ContactManager.IndexModel)" %>
<%@ Import Namespace="ContactManager" %>
<asp:Content ID="Content1" ContentPlaceHolderID="head" runat="server">
<title>Index</title>
</asp:Content>

<asp:Content ID="Content2" ContentPlaceHolderID="MainContent" runat="server">

<ul id="leftColumn">
<% For Each item in Model.Groups %>
    <li <%= Html.Selected(item.Id, Model.SelectedGroup.Id) %>>
    <%= Ajax.ActionLink(item.Name, "Index", New With { .id = item.Id }, New AjaxOptions With { .UpdateTargetId
= "divContactList"})%>
    </li>
<% Next %>
</ul>
<div id="divContactList">
    <% Html.RenderPartial("ContactList", Model.SelectedGroup) %>
</div>

<div class="divContactList-bottom"> </div>
</asp:Content>
```

There are two things that you should notice about the updated view in Listing 2. First, notice that all of the content moved into the partial is replaced with a call to Html.RenderPartial(). The Html.RenderPartial() method is called when the Index view is first requested in order to display the initial set of contacts.

Second, notice that the Html.ActionLink() used to display contact groups has been replaced with an Ajax.ActionLink(). The Ajax.ActionLink() is called with the following parameters:

```
<%= Ajax.ActionLink(item.Name, "Index", New With { .id = item.Id }, New AjaxOptions With { .UpdateTargetId =
"divContactList"})%>
```

The first parameter represents the text to display for the link, the second parameter represents the route values, and the third parameter represents the Ajax options. In this case, we use the UpdateTargetId Ajax option to point to the HTML tag that we want to update after the Ajax request completes. We want to update the tag with the new list of contacts.

The updated Index() method of the Contact controller is contained in Listing 3.

Listing 3 - Controllers\ContactController.vb (Index method)

```
Public Function Index(ByVal id As Integer?) As ActionResult
    ' Get selected group
    Dim selectedGroup = _service.GetGroup(id)
    if IsNothing(selectedGroup) Then
        Return RedirectToAction("Index", "Group")
    End If

    ' Normal Request
    if Not Request.IsAjaxRequest() Then
        Dim model As new IndexModel With { _
            .Groups = _service.ListGroups(), _
            .SelectedGroup = selectedGroup _
        }
        Return View("Index", model)
    End If

    ' Ajax Request
    return PartialView("ContactList", selectedGroup)
End Function
```

The updated Index() action conditionally returns one of two things. If the Index() action is invoked by an Ajax request then the controller returns a partial. Otherwise, the Index() action returns an entire view.

Notice that the Index() action does not need to return as much data when invoked by an Ajax request. In the context of a normal request, the Index action returns a list of all of the contact groups and the selected contact group. In the context of an Ajax request, the Index() action returns only the selected group. Ajax means less work on your database server.

Our modified Index view works in the case of both uplevel and downlevel browsers. If you click a contact group, and your browser supports JavaScript, then only the region of the view that contains the list of contacts is updated. If, on the other hand, your browser does not support JavaScript, then the entire view is updated.

Our updated Index view has one problem. When you click a contact group, the selected group is not highlighted. Because the list of groups is displayed outside of the region that is updated during an Ajax request, the right group does not get highlighted. We'll fix this issue in the next section.

Adding jQuery Animation Effects

Normally, when you click a link in a web page, you can use the browser progress bar to detect whether or not the browser is actively fetching the updated content. When performing an Ajax request, on the other hand, the browser progress bar does not show any progress. This can make users nervous. How do you know whether the browser has frozen?

There are several ways that you can indicate to a user that work is being performed while performing an Ajax request. One approach is to display a simple animation. For example, you can fade out a region when an Ajax request begins and fade in the region when the request completes.

We'll use the jQuery library which is included with the Microsoft ASP.NET MVC framework, to create the animation effects. The updated Index view is contained in Listing 4.

Listing 4 - Views\Contact\Index.aspx

```
<%@ Page Title="" Language="VB" MasterPageFile="~/Views/Shared/Site.Master"
Inherits="System.Web.Mvc.ViewPage(Of ContactManager.IndexModel)" %>
<%@ Import Namespace="ContactManager" %>
<asp:Content ID="Content1" ContentPlaceHolderID="head" runat="server">
<title>Index</title>
</asp:Content>

<asp:Content ID="Content2" ContentPlaceHolderID="MainContent" runat="server">

<script type="text/javascript">

    function beginContactList(args)
    {
        // Highlight selected group
        $('#leftColumn li').removeClass('selected');
        $(this).parent().addClass('selected');

        // Animate
        $('#divContactList').fadeOut('normal');
    }

    function successContactList()
    {
        // Animate
        $('#divContactList').fadeIn('normal');
    }

    function failureContactList()
    {
        alert("Could not retrieve contacts.");
    }

</script>

<ul id="leftColumn">
<% For Each item in Model.Groups %>
    <li <%= Html.Selected(item.Id, Model.SelectedGroup.Id) %>>
    <%= Ajax.ActionLink(item.Name, "Index", New With { .id = item.Id }, New AjaxOptions With { .UpdateTargetId
= "divContactList", .OnBegin = "beginContactList", .OnSuccess = "successContactList", .OnFailure =
"failureContactList" })%>
    </li>
<% Next %>
</ul>
<div id="divContactList">
    <% Html.RenderPartial("ContactList", Model.SelectedGroup) %>
</div>

<div class="divContactList-bottom"> </div>
</asp:Content>
```

Notice that the updated Index view contains three new JavaScript functions. The first two functions use jQuery to fade out and fade in the list of contacts when you click a new contact group. The third function displays an error message when an Ajax request results in an error (for example, network timeout).

The first function also takes care of highlighting the selected group. A class= selected attribute is added to the parent element (the LI element) of the element clicked. Again, jQuery makes it easy to select the right element and add the CSS class.

These scripts are tied to the group links with the help of the Ajax.ActionLink() AjaxOptions parameter. The updated Ajax.ActionLink() method call looks like this:

```
<%= Ajax.ActionLink(item.Name, "Index", New With { .id = item.Id }, New AjaxOptions With { .UpdateTargetId =
"divContactList", .OnBegin = "beginContactList", .OnSuccess = "successContactList", .OnFailure =
"failureContactList" })%>
```

Adding Browser History Support

Normally, when you click a link to update a page, your browser history is updated. That way, you can click the browser Back button to move back in time to the previous state of the page. For example, if you click the Friends contact group and then click the Business contact group, you can click the browser Back button to navigate back to the state of the page when the Friends contact group was selected.

Unfortunately, performing an Ajax request does not update browser history automatically. If you click a contact group, and the list of matching contacts is retrieved with an Ajax request, then the browser history is not updated. You cannot use the browser Back button to navigate back to a contact group after selecting a new contact group.

If you want users to be able to use the browser Back button after performing Ajax requests then you need to perform a little more work. You need to take advantage of the browser history management functionality built in the ASP.NET AJAX Framework.

ASP.NET AJAX browser history, you need to do three things:

1. Enable Browser History by setting the enableBrowserHistory property to true.
2. Save history points when the state of a view changes by calling the addHistoryPoint() method.
3. Reconstruct the state of the view when the navigate event is raised.

The updated Index view is contained in Listing 5.

Listing 5 - Views\Contact\Index.aspx

```
<%@ Page Title="" Language="VB" MasterPageFile="~/Views/Shared/Site.Master"
Inherits="System.Web.Mvc.ViewPage(Of ContactManager.IndexModel)" %>
<%@ Import Namespace="ContactManager" %>
<asp:Content ID="Content1" ContentPlaceHolderID="head" runat="server">
<title>Index</title>
</asp:Content>

<asp:Content ID="Content2" ContentPlaceHolderID="MainContent" runat="server">

<script type="text/javascript">

    var _currentGroupId = -1;

    Sys.Application.add_init(pageInit);

    function pageInit() {
        // Enable history
        Sys.Application.set_enableHistory(true);

        // Add Handler for history
        Sys.Application.add_navigate(navigate);
    }

    function navigate(sender, e) {
        // Get groupId from address bar
        var groupId = e.get_state().groupId;

        // If groupId != currentGroupId then navigate
        if (groupId != _currentGroupId) {
            _currentGroupId = groupId;
            $("#divContactList").load("/Contact/Index/" + groupId);
            selectGroup(groupId);
```

```
        }
    }

    function selectGroup(groupId) {
        $('#leftColumn li').removeClass('selected');
        if (groupId)
            $('a[groupid=' + groupId + ']').parent().addClass('selected');
        else
            $('#leftColumn li:first').addClass('selected');
    }

    function beginContactList(args) {
        // Highlight selected group
        _currentGroupId = this.getAttribute("groupid");
        selectGroup(_currentGroupId);

        // Add history point
        Sys.Application.addHistoryPoint({ "groupId": _currentGroupId });

        // Animate
        $('#divContactList').fadeOut('normal');
    }

    function successContactList() {
        // Animate
        $('#divContactList').fadeIn('normal');
    }

    function failureContactList() {
        alert("Could not retrieve contacts.");
    }

</script>

<ul id="leftColumn">
<% For Each item in Model.Groups %>
    <li <%= Html.Selected(item.Id, Model.SelectedGroup.Id) %>>
    <%= Ajax.ActionLink(item.Name, "Index", New With { .id = item.Id }, New AjaxOptions With { .UpdateTargetId
= "divContactList", .OnBegin = "beginContactList", .OnSuccess = "successContactList", .OnFailure =
"failureContactList" }, New With { .groupid = item.Id })%>
    </li>
<% Next %>
</ul>
<div id="divContactList">
    <% Html.RenderPartial("ContactList", Model.SelectedGroup) %>
</div>

<div class="divContactList-bottom"> </div>
</asp:Content>
```

In Listing 5, Browser History is enabled in the pageInit() function. The pageInit() function is also used to set up the event handler for the navigate event. The navigate event is raised whenever the browser Forward or Back button causes the state of the page to change.

The beginContactList() method is called when you click a contact group. This method creates a new history point by calling the addHistoryPoint() method. The id of the contact group clicked is added to history.

The group id is retrieved from an expando attribute on the contact group link. The link is rendered with the following call to Ajax.ActionLink().

```
<%= Ajax.ActionLink(item.Name, "Index", New With { .id = item.Id }, New AjaxOptions With { .UpdateTargetId =
"divContactList", .OnBegin = "beginContactList", .OnSuccess = "successContactList", .OnFailure =
"failureContactList" }, New With { .groupid = item.Id })%>
```

The last parameter passed to the Ajax.ActionLink() adds an expando attribute named groupid to the link (lowercase

for XHTML compatibility).

When a user hits the browser Back or Forward button, the navigate event is raised and the navigate() method is called. This method updates the contacts displayed in the page to match the state of the page that corresponds to the browser history point passed to the navigate method.

Performing Ajax Deletes

Currently, in order to delete a contact, you need to click on the Delete link and then click the Delete button displayed in the delete confirmation page (see Figure 2). This seems like a lot of page requests to do something simple like deleting a database record.

Figure 02: The delete confirmation page(Click to view full-size image)

It is tempting to skip the delete confirmation page and delete a contact directly from the Index view. You should avoid this temptation because taking this approach opens your application to security holes. In general, you don t want to perform an HTTP GET operation when invoking an action that modifies the state of your web application. When performing a delete, you want to perform an HTTP POST, or better yet, an HTTP DELETE operation.

The Delete link is contained in the ContactList partial. An updated version of the ContactList partial is contained in Listing 6.

Listing 6 - Views\Contact\ContactList.ascx

```
<%@ Control Language="VB" Inherits="System.Web.Mvc.ViewUserControl(Of ContactManager.Group)" %>
<%@ Import Namespace="ContactManager" %>
<table class="data-table" cellpadding="0" cellspacing="0">
    <thead>
        <tr>
            <th class="actions edit">
                Edit
            </th>
            <th class="actions delete">
                Delete
            </th>
            <th>
                Name
            </th>
            <th>
                Phone
            </th>
            <th>
                Email
            </th>
        </tr>
    </thead>
    <tbody>
        <% For Each item in Model.Contacts %>
        <tr>
            <td class="actions edit">
                <a href='<%= Url.Action("Edit", New With {.id=item.Id}) %>'><img src="../../Content/Edit.png"
alt="Edit" /></a>
            </td>
            <td class="actions delete">
                <%= Ajax.ImageActionLink("../../Content/Delete.png", "Delete", "Delete", New with { .id =
item.Id }, New AjaxOptions With { .Confirm = "Delete contact?", .HttpMethod = "Delete", .UpdateTargetId =
"divContactList" })%>
            </td>
            <th>
                <%= Html.Encode(item.FirstName) %>
                <%= Html.Encode(item.LastName) %>
            </th>
            <td>
                <%= Html.Encode(item.Phone) %>
            </td>
            <td>
                <%= Html.Encode(item.Email) %>
            </td>
        </tr>
        <% Next %>
    </tbody>
</table>
```

The Delete link is rendered with the following call to the Ajax.ImageActionLink() method:

```
<%= Ajax.ImageActionLink("../../Content/Delete.png", "Delete", "Delete", New with { .id = item.Id }, New
AjaxOptions With { .Confirm = "Delete contact?", .HttpMethod = "Delete", .UpdateTargetId = "divContactList"
})%<
```

NOTE

The Ajax.ImageActionLink() is not a standard part of the ASP.NET MVC framework. The Ajax.ImageActionLink() is a custom helper methods included in the Contact Manager project.

The AjaxOptions parameter has two properties. First, the Confirm property is used to display a popup JavaScript confirmation dialog. Second, the HttpMethod property is used to perform an HTTP DELETE operation.

Listing 7 contains a new AjaxDelete() action that has been added to the Contact controller.

Listing 7 - Controllers\ContactController.vb (AjaxDelete)

```
<AcceptVerbs(HttpVerbs.Delete), ActionName("Delete")> _
Public Function AjaxDelete(ByVal id As Integer) As ActionResult
    ' Get contact and group
    Dim contactToDelete = _service.GetContact(id)
    Dim selectedGroup = _service.GetGroup(contactToDelete.Group.Id)

    ' Delete from database
    _service.DeleteContact(contactToDelete)

    ' Return Contact List
    Return PartialView("ContactList", selectedGroup)
End Function
```

The AjaxDelete() action is decorated with an AcceptVerbs attribute. This attribute prevents the action from being invoked except by any HTTP operation other than an HTTP DELETE operation. In particular, you cannot invoke this action with an HTTP GET.

After you delete database record, you need to display the updated list of contacts that does not contain the deleted record. The AjaxDelete() method returns the ContactList partial and the updated list of contacts.

Summary

In this iteration, we added Ajax functionality to our Contact Manager application. We used Ajax to improve the responsiveness and performance of our application.

First, we refactored the Index view so that clicking a contact group does not update the entire view. Instead, clicking a contact group only updates the list of contacts.

Next, we used jQuery animation effects to fade out and fade in the list of contacts. Adding animation to an Ajax application can be used to provide users of the application with the equivalent of a browser progress bar.

We also added browser history support to our Ajax application. We enabled users to click the browser Back and Forward buttons to change the state of the Index view.

Finally, we created a delete link that supports HTTP DELETE operations. By performing Ajax deletes, we enable users to delete database records without requiring the user to request an additional delete confirmation page.

NerdDinner Tutorial

The best way to learn a new framework is to build something with it. This tutorial walks through how to build a small, but complete, application using ASP.NET MVC, and introduces some of the core concepts behind it.

The application we are going to build is called "NerdDinner". NerdDinner provides an easy way for people to find and organize dinners online:

NerdDinner enables registered users to create, edit and delete dinners. It enforces a consistent set of validation and business rules across the application:

Visitors can use an AJAX-based map to search for upcoming dinners being held near them:

Clicking a dinner will take them to a details page where they can learn more about it:

If they are interested in attending the dinner they can login or register on the site:

They can then click an AJAX-based RSVP link to attend the event:

Implementing NerdDinner

We are going to begin our NerdDinner application by using the File->New Project command within Visual Studio to create a brand new ASP.NET MVC project. We will then incrementally add functionality and features. Along the way we'll cover:

1. How to create a new ASP.NET MVC Project
2. How to create a database
3. How to build a model with business rule validations
4. How to use controllers and views to implement a listing/details UI
5. How to provide CRUD (create, read, update, delete) data form entry support
6. How to use ViewData and implement ViewModel classes
7. How to re-use UI using master pages and partials
8. How to implement efficient data paging
9. How to secure applications using authentication and authorization

10. How to use AJAX to deliver dynamic updates
11. How to use AJAX to implement mapping scenarios
12. How to enable automated unit testing

You can build your own copy of NerdDinner from scratch by completing each step we walkthrough in this chapter. Alternatively, you can download a completed version of the source code here: NerdDinner on GitHub. You can also optionally also download a free PDF version of this tutorial if you want to read the tutorial offline.

You can use either Visual Studio 2008 or the free Visual Web Developer 2008 Express to build the application. You can use either SQL Server or the free SQL Server Express for the database.

You can install ASP.NET MVC, Visual Web Developer 2008 Express, and SQL Server Express (all free) using V2 of the Microsoft Web Platform Installer

Now let's get started....

Now that we've covered what NerdDinner is, let's roll up our sleeves and write some code.

We'll begin by using File->New Project within Visual Studio to create the NerdDinner application.

> This is step 1 of a free "NerdDinner" application tutorial that walks-through how to build a small, but complete, web application using ASP.NET MVC 1.
>
> Step 1 shows you how to put the basic NerdDinner application structure in place.
>
> If you are using ASP.NET MVC 3, we recommend you follow the Getting Started With MVC 3 or MVC Music Store tutorials.

NerdDinner Step 1: File->New Project

We'll begin our NerdDinner application by selecting the **File->New Project** menu item within either Visual Studio 2008 or the free Visual Web Developer 2008 Express.

This will bring up the "New Project" dialog. To create a new ASP.NET MVC application, we'll select the "Web" node on the left-hand side of the dialog and then choose the "ASP.NET MVC Web Application" project template on the right:

Important: Make sure you've downloaded and installed ASP.NET MVC - otherwise it won't show up in the New Project dialog. You can use V2 of the Microsoft Web Platform Installer if you haven't installed it yet (ASP.NET MVC is available within the "Web Platform->Frameworks and Runtimes" section).

We'll name the new project we are going to create "NerdDinner" and then click the "ok" button to create it.

When we click "ok" Visual Studio will bring up an additional dialog that prompts us to optionally create a unit test project for the new application as well. This unit test project enables us to create automated tests that verify the functionality and behavior of our application (something we'll cover how to-do later in this tutorial).

The "Test framework" dropdown in the above dialog is populated with all available ASP.NET MVC unit test project templates installed on the machine. Versions can be downloaded for NUnit, MBUnit, and XUnit. The built-in Visual Studio Unit Test framework is also supported.

Note: The Visual Studio Unit Test Framework is only available with Visual Studio 2008 Professional and higher versions. If you are using VS 2008 Standard Edition or Visual Web Developer 2008 Express you will need to download and install the NUnit, MBUnit or XUnit extensions for ASP.NET MVC in order for this dialog to be shown. The dialog will not display if there aren't any test frameworks installed.

We'll use the default "NerdDinner.Tests" name for the test project we create, and use the "Visual Studio Unit Test" framework option. When we click the "ok" button Visual Studio will create a solution for us with two projects in it - one for our web application and one for our unit tests:

Examining the NerdDinner directory structure

When you create a new ASP.NET MVC application with Visual Studio, it automatically adds a number of files and directories to the project:

ASP.NET MVC projects by default have six top-level directories:

DIRECTORY	PURPOSE
/Controllers	Where you put Controller classes that handle URL requests
/Models	Where you put classes that represent and manipulate data
/Views	Where you put UI template files that are responsible for rendering output
/Scripts	Where you put JavaScript library files and scripts (.js)
/Content	Where you put CSS and image files, and other non-dynamic/non-JavaScript content
/App_Data	Where you store data files you want to read/write.

ASP.NET MVC does not require this structure. In fact, developers working on large applications will typically partition the application up across multiple projects to make it more manageable (for example: data model classes often go in a separate class library project from the web application). The default project structure, however, does provide a nice default directory convention that we can use to keep our application concerns clean.

When we expand the /Controllers directory we'll find that Visual Studio added two controller classes – HomeController and AccountController – by default to the project:

When we expand the /Views directory, we'll find three sub-directories – /Home, /Account and /Shared – as well as several template files within them were also added to the project by default:

When we expand the /Content and /Scripts directories, we'll find a Site.css file that is used to style all HTML on the site, as well as JavaScript libraries that can enable ASP.NET AJAX and jQuery support within the application:

When we expand the NerdDinner.Tests project we'll find two classes that contain unit tests for our controller classes:

These default files added by Visual Studio provide us with a basic structure for a working application - complete with home page, about page, account login/logout/registration pages, and an unhandled error page (all wired-up and working out of the box).

Running the NerdDinner Application

We can run the project by choosing either the **Debug->Start Debugging** or **Debug->Start Without Debugging** menu items:

This will launch the built-in ASP.NET Web-server that comes with Visual Studio, and run our application:

Below is the home page for our new project (URL: "/") when it runs:

Clicking the "About" tab displays an about page (URL: "/Home/About"):

Clicking the "Log On" link on the top-right takes us to a Login page (URL: "/Account/LogOn")

If we don't have a login account we can click the register link (URL: "/Account/Register") to create one:

The code to implement the above home, about, and logout/ register functionality was added by default when we created our new project. We'll use it as the starting point of our application.

Testing the NerdDinner Application

If we are using the Professional Edition or higher version of Visual Studio 2008, we can use the built-in unit testing IDE support within Visual Studio to test the project:

Choosing one of the above options will open the "Test Results" pane within the IDE and provide us with pass/fail status on the 27 unit tests included in our new project that cover the built-in functionality:

Later in this tutorial we'll talk more about automated testing and add additional unit tests that cover the application functionality we implement.

Next Step

We've now got a basic application structure in place. Let's now create a database to store our application data.

This is step 2 of a free "NerdDinner" application tutorial that walks-through how to build a small, but complete, web application using ASP.NET MVC 1.

Step 2 shows the steps to create the database holding all of the dinner and RSVP data for our NerdDinner application.

If you are using ASP.NET MVC 3, we recommend you follow the Getting Started With MVC 3 or MVC Music Store tutorials.

NerdDinner Step 2: Creating the Database

We'll be using a database to store all of the Dinner and RSVP data for our NerdDinner application.

The steps below show creating the database using the free SQL Server Express edition (which you can easily install using V2 of the Microsoft Web Platform Installer). All of the code we'll write works with both SQL Server Express and the full SQL Server.

Creating a new SQL Server Express database

We'll begin by right-clicking on our web project, and then select the **Add->New Item** menu command:

This will bring up Visual Studio's "Add New Item" dialog. We'll filter by the "Data" category and select the "SQL Server Database" item template:

We'll name the SQL Server Express database we want to create "NerdDinner.mdf" and hit ok. Visual Studio will then ask us if we want to add this file to our \App_Data directory (which is a directory already setup with both read and write security ACLs):

We'll click "Yes" and our new database will be created and added to our Solution Explorer:

Creating Tables within our Database

We now have a new empty database. Let's add some tables to it.

To do this we'll navigate to the "Server Explorer" tab window within Visual Studio, which enables us to manage databases and servers. SQL Server Express databases stored in the \App_Data folder of our application will automatically show up within the Server Explorer. We can optionally use the "Connect to Database" icon on the top of the "Server Explorer" window to add additional SQL Server databases (both local and remote) to the list as well:

We will add two tables to our NerdDinner database – one to store our Dinners, and the other to track RSVP acceptances to them. We can create new tables by right-clicking on the "Tables" folder within our database and choosing the "Add New Table" menu command:

This will open up a table designer that allows us to configure the schema of our table. For our "Dinners" table we will add 10 columns of data:

We want the "DinnerID" column to be a unique primary key for the table. We can configure this by right-clicking on the "DinnerID" column and choosing the "Set Primary Key" menu item:

In addition to making DinnerID a primary key, we also want configure it as an "identity" column whose value is automatically incremented as new rows of data are added to the table (meaning the first inserted Dinner row will have a DinnerID of 1, the second inserted row will have a DinnerID of 2, etc).

We can do this by selecting the "DinnerID" column and then use the "Column Properties" editor to set the "(Is Identity)" property on the column to "Yes". We will use the standard identity defaults (start at 1 and increment 1 on each new Dinner row):

We'll then save our table by typing Ctrl-S or by using the **File->Save** menu command. This will prompt us to name the table. We'll name it "Dinners":

Our new Dinners table will then show up within our database in the server explorer.

We'll then repeat the above steps and create a "RSVP" table. This table with have 3 columns. We will setup the RsvpID column as the primary key, and also make it an identity column:

We'll save it and give it the name "RSVP".

Setting up a Foreign Key Relationship between Tables

We now have two tables within our database. Our last schema design step will be to setup a "one-to-many" relationship between these two tables – so that we can associate each Dinner row with zero or more RSVP rows that apply to it. We will do this by configuring the RSVP table's "DinnerID" column to have a foreign-key relationship to the "DinnerID" column in the "Dinners" table.

To do this we'll open up the RSVP table within the table designer by double-clicking it in the server explorer. We'll then select the "DinnerID" column within it, right-click, and choose the "Relationships..." context menu command:

This will bring up a dialog that we can use to setup relationships between tables:

We'll click the "Add" button to add a new relationship to the dialog. Once a relationship has been added, we'll

expand the "Tables and Column Specification" tree-view node within the property grid to the right of the dialog, and then click the "..." button to the right of it:

Clicking the "..." button will bring up another dialog that allows us to specify which tables and columns are involved in the relationship, as well as allow us to name the relationship.

We will change the Primary Key Table to be "Dinners", and select the "DinnerID" column within the Dinners table as the primary key. Our RSVP table will be the foreign-key table, and the RSVP.DinnerID column will be associated as the foreign-key:

Now each row in the RSVP table will be associated with a row in the Dinner table. SQL Server will maintain referential integrity for us – and prevent us from adding a new RSVP row if it does not point to a valid Dinner row. It will also prevent us from deleting a Dinner row if there are still RSVP rows referring to it.

Adding Data to our Tables

Let's finish by adding some sample data to our Dinners table. We can add data to a table by right-clicking on it within the Server Explorer and choosing the "Show Table Data" command:

We'll add a few rows of Dinner data that we can use later as we start implementing the application:

Next Step

We've finished creating our database. Let's now create model classes that we can use to query and update it.

> This is step 3 of a free "NerdDinner" application tutorial that walks-through how to build a small, but complete, web application using ASP.NET MVC 1.
>
> Step 3 shows how to create a model that we can use to both query and update the database for our NerdDinner application.
>
> If you are using ASP.NET MVC 3, we recommend you follow the Getting Started With MVC 3 or MVC Music Store tutorials.

NerdDinner Step 3: Building the Model

In a model-view-controller framework the term "model" refers to the objects that represent the data of the application, as well as the corresponding domain logic that integrates validation and business rules with it. The model is in many ways the "heart" of an MVC-based application, and as we'll see later fundamentally drives the behavior of it.

The ASP.NET MVC framework supports using any data access technology, and developers can choose from a variety of rich .NET data options to implement their models including: LINQ to Entities, LINQ to SQL, NHibernate, LLBLGen Pro, SubSonic, WilsonORM, or just raw ADO.NET DataReaders or DataSets.

For our NerdDinner application we are going to use LINQ to SQL to create a simple model that corresponds fairly closely to our database design, and adds some custom validation logic and business rules. We will then implement a repository class that helps abstract away the data persistence implementation from the rest of the application, and enables us to easily unit test it.

LINQ to SQL

LINQ to SQL is an ORM (object relational mapper) that ships as part of .NET 3.5.

LINQ to SQL provides an easy way to map database tables to .NET classes we can code against. For our NerdDinner application we'll use it to map the Dinners and RSVP tables within our database to Dinner and RSVP classes. The columns of the Dinners and RSVP tables will correspond to properties on the Dinner and RSVP classes. Each Dinner and RSVP object will represent a separate row within the Dinners or RSVP tables in the database.

LINQ to SQL allows us to avoid having to manually construct SQL statements to retrieve and update Dinner and RSVP objects with database data. Instead, we'll define the Dinner and RSVP classes, how they map to/from the database, and the relationships between them. LINQ to SQL will then takes care of generating the appropriate SQL execution logic to use at runtime when we interact and use them.

We can use the LINQ language support within VB and C# to write expressive queries that retrieve Dinner and RSVP objects from the database. This minimizes the amount of data code we need to write, and allows us to build really clean applications.

Adding LINQ to SQL Classes to our project

We'll begin by right-clicking on the "Models" folder within our project, and select the **Add->New Item** menu command:

This will bring up the "Add New Item" dialog. We'll filter by the "Data" category and select the "LINQ to SQL Classes" template within it:

We'll name the item "NerdDinner" and click the "Add" button. Visual Studio will add a NerdDinner.dbml file under our \Models directory, and then open the LINQ to SQL object relational designer:

Creating Data Model Classes with LINQ to SQL

LINQ to SQL enables us to quickly create data model classes from existing database schema. To-do this we'll open the NerdDinner database in the Server Explorer, and select the Tables we want to model in it:

We can then drag the tables onto the LINQ to SQL designer surface. When we do this LINQ to SQL will automatically create Dinner and RSVP classes using the schema of the tables (with class properties that map to the database table columns):

By default the LINQ to SQL designer automatically "pluralizes" table and column names when it creates classes based on a database schema. For example: the "Dinners" table in our example above resulted in a "Dinner" class. This class naming helps make our models consistent with .NET naming conventions, and I usually find that having the designer fix this up convenient (especially when adding lots of tables). If you don't like the name of a class or property that the designer generates, though, you can always override it and change it to any name you want. You can do this either by editing the entity/property name in-line within the designer or by modifying it via the property grid.

By default the LINQ to SQL designer also inspects the primary key/foreign key relationships of the tables, and based on them automatically creates default "relationship associations" between the different model classes it creates. For example, when we dragged the Dinners and RSVP tables onto the LINQ to SQL designer a one-to-many relationship association between the two was inferred based on the fact that the RSVP table had a foreign-key to the Dinners table (this is indicated by the arrow in the designer):

The above association will cause LINQ to SQL to add a strongly typed "Dinner" property to the RSVP class that developers can use to access the Dinner associated with a given RSVP. It will also cause the Dinner class to have a "RSVPs" collection property that enables developers to retrieve and update RSVP objects associated with a particular Dinner.

Below you can see an example of intellisense within Visual Studio when we create a new RSVP object and add it to a Dinner's RSVPs collection. Notice how LINQ to SQL automatically added a "RSVPs" collection on the Dinner object:

```
Dinner dinner = db.Dinners.Single(d => d.DinnerID == 1);

RSVP myRSVP = new RSVP();
myRSVP.AttendeeName = "ScottGu";

dinner.R
```

By adding the RSVP object to the Dinner's RSVPs collection we are telling LINQ to SQL to associate a foreign-key relationship between the Dinner and the RSVP row in our database:

```
Dinner dinner = db.Dinners.Single(d => d.DinnerID == 1);

RSVP myRSVP = new RSVP();
myRSVP.AttendeeName = "ScottGu";

dinner.RSVPs.Add(myRSVP);
```

If you don't like how the designer has modeled or named a table association, you can override it. Just click on the association arrow within the designer and access its properties via the property grid to rename, delete or modify it. For our NerdDinner application, though, the default association rules work well for the data model classes we are building and we can just use the default behavior.

NerdDinnerDataContext Class

Visual Studio will automatically create .NET classes that represent the models and database relationships defined using the LINQ to SQL designer. A LINQ to SQL DataContext class is also generated for each LINQ to SQL designer file added to the solution. Because we named our LINQ to SQL class item "NerdDinner", the DataContext class created will be called "NerdDinnerDataContext". This NerdDinnerDataContext class is the primary way we will interact with the database.

Our NerdDinnerDataContext class exposes two properties - "Dinners" and "RSVPs" - that represent the two tables we modeled within the database. We can use C# to write LINQ queries against those properties to query and retrieve Dinner and RSVP objects from the database.

The following code demonstrates how to instantiate a NerdDinnerDataContext object and perform a LINQ query against it to obtain a sequence of Dinners that occur in the future. Visual Studio provides full intellisense when writing the LINQ query, and the objects returned from it are strongly-typed and also support intellisense:

```
NerdDinnerDataContext db = new NerdDinnerDataContext();

var upcomingDinners = from dinner in db.Dinners
                      where dinner.EventDate > DateTime.Now
                      orderby dinner.EventDate
                      select dinner;

foreach (Dinner dinner in upcomingDinners) {
    dinner.
}
```

Description
DinnerID
Equals
EventDate
GetErrors
GetHashCode
GetType
HostedBy
Latitude

string Dinner.Description

In addition to allowing us to query for Dinner and RSVP objects, a NerdDinnerDataContext also automatically tracks any changes we subsequently make to the Dinner and RSVP objects we retrieve through it. We can use this functionality to easily save the changes back to the database - without having to write any explicit SQL update code.

For example, the code below demonstrates how to use a LINQ query to retrieve a single Dinner object from the database, update two of the Dinner properties, and then save the changes back to the database:

```
NerdDinnerDataContext db = new NerdDinnerDataContext();

// Retrieve Dinner object that reprents row with DinnerID of 1
Dinner dinner = db.Dinners.Single(d => d.DinnerID == 1);

// Update two properties on Dinner
dinner.Title = "Changed Title";
dinner.Description = "This dinner will be fun";

// Persist changes to database
db.SubmitChanges();
```

The NerdDinnerDataContext object in the code above automatically tracked the property changes made to the Dinner object we retrieved from it. When we called the "SubmitChanges()" method, it will execute an appropriate SQL "UPDATE" statement to the database to persist the updated values back.

Creating a DinnerRepository Class

For small applications it is sometimes fine to have Controllers work directly against a LINQ to SQL DataContext class, and embed LINQ queries within the Controllers. As applications get larger, though, this approach becomes cumbersome to maintain and test. It can also lead to us duplicating the same LINQ queries in multiple places.

One approach that can make applications easier to maintain and test is to use a "repository" pattern. A repository class helps encapsulate data querying and persistence logic, and abstracts away the implementation details of the data persistence from the application. In addition to making application code cleaner, using a repository pattern can make it easier to change data storage implementations in the future, and it can help facilitate unit testing an application without requiring a real database.

For our NerdDinner application we'll define a DinnerRepository class with the below signature:

```
public class DinnerRepository {

    // Query Methods
    public IQueryable<Dinner> FindAllDinners();
    public IQueryable<Dinner> FindUpcomingDinners();
    public Dinner             GetDinner(int id);

    // Insert/Delete
    public void Add(Dinner dinner);
    public void Delete(Dinner dinner);

    // Persistence
    public void Save();
}
```

Note: Later in this chapter we'll extract an IDinnerRepository interface from this class and enable dependency injection with it on our Controllers. To begin with, though, we are going to start simple and just work directly with the DinnerRepository class.

To implement this class we'll right-click on our "Models" folder and choose the **Add->New Item** menu command. Within the "Add New Item" dialog we'll select the "Class" template and name the file "DinnerRepository.cs":

We can then implement our DinnerRepository class using the code below:

```
public class DinnerRepository {

    private NerdDinnerDataContext db = new NerdDinnerDataContext();

    //
    // Query Methods

    public IQueryable<Dinner> FindAllDinners() {
        return db.Dinners;
    }

    public IQueryable<Dinner> FindUpcomingDinners() {
        return from dinner in db.Dinners
               where dinner.EventDate > DateTime.Now
               orderby dinner.EventDate
               select dinner;
    }

    public Dinner GetDinner(int id) {
        return db.Dinners.SingleOrDefault(d => d.DinnerID == id);
    }

    //
    // Insert/Delete Methods

    public void Add(Dinner dinner) {
        db.Dinners.InsertOnSubmit(dinner);
    }

    public void Delete(Dinner dinner) {
        db.RSVPs.DeleteAllOnSubmit(dinner.RSVPs);
        db.Dinners.DeleteOnSubmit(dinner);
    }

    //
    // Persistence

    public void Save() {
        db.SubmitChanges();
    }
}
```

Retrieving, Updating, Inserting and Deleting using the DinnerRepository class

Now that we've created our DinnerRepository class, let's look at a few code examples that demonstrate common tasks we can do with it:

Querying Examples

The code below retrieves a single Dinner using the DinnerID value:

```
DinnerRepository dinnerRepository = new DinnerRepository();

// Retrieve specific dinner by its DinnerID
Dinner dinner = dinnerRepository.GetDinner(5);
```

The code below retrieves all upcoming dinners and loops over them:

```
DinnerRepository dinnerRepository = new DinnerRepository();

// Retrieve all upcoming Dinners
var upcomingDinners = dinnerRepository.FindUpcomingDinners();

// Loop over each upcoming Dinner and print out its Title
foreach (Dinner dinner in upcomingDinners) {
   Response.Write("Title" + dinner.Title);
}
```

Insert and Update Examples

The code below demonstrates adding two new dinners. Additions/modifications to the repository aren't committed to the database until the "Save()" method is called on it. LINQ to SQL automatically wraps all changes in a database transaction – so either all changes happen or none of them do when our repository saves:

```
DinnerRepository dinnerRepository = new DinnerRepository();

// Create First Dinner
Dinner newDinner1 = new Dinner();
newDinner1.Title = "Dinner with Scott";
newDinner1.HostedBy = "ScotGu";
newDinner1.ContactPhone = "425-703-8072";

// Create Second Dinner
Dinner newDinner2 = new Dinner();
newDinner2.Title = "Dinner with Bill";
newDinner2.HostedBy = "BillG";
newDinner2.ContactPhone = "425-555-5151";

// Add Dinners to Repository
dinnerRepository.Add(newDinner1);
dinnerRepository.Add(newDinner2);

// Persist Changes
dinnerRepository.Save();
```

The code below retrieves an existing Dinner object, and modifies two properties on it. The changes are committed back to the database when the "Save()" method is called on our repository:

```
DinnerRepository dinnerRepository = new DinnerRepository();

// Retrieve specific dinner by its DinnerID
Dinner dinner = dinnerRepository.GetDinner(5);

// Update Dinner properties
dinner.Title = "Update Title";
dinner.HostedBy = "New Owner";

// Persist changes
dinnerRepository.Save();
```

The code below retrieves a dinner and then adds an RSVP to it. It does this using the RSVPs collection on the Dinner object that LINQ to SQL created for us (because there is a primary-key/foreign-key relationship between the two in the database). This change is persisted back to the database as a new RSVP table row when the "Save()" method is called on the repository:

```
DinnerRepository dinnerRepository = new DinnerRepository();

// Retrieve specific dinner by its DinnerID
Dinner dinner = dinnerRepository.GetDinner(5);

// Create a new RSVP object
RSVP myRSVP = new RSVP();
myRSVP.AttendeeName = "ScottGu";

// Add RSVP to Dinner's RSVP Collection
dinner.RSVPs.Add(myRSVP);

// Persist changes
dinnerRepository.Save();
```

Delete Example

The code below retrieves an existing Dinner object, and then marks it to be deleted. When the "Save()" method is called on the repository it will commit the delete back to the database:

```
DinnerRepository dinnerRepository = new DinnerRepository();

// Retrieve specific dinner by its DinnerID
Dinner dinner = dinnerRepository.GetDinner(5);

// Mark dinner to be deleted
dinnerRepository.Delete(dinner);

// Persist changes
dinnerRepository.Save();
```

Integrating Validation and Business Rule Logic with Model Classes

Integrating validation and business rule logic is a key part of any application that works with data.

Schema Validation

When model classes are defined using the LINQ to SQL designer, the datatypes of the properties in the data model classes correspond to the datatypes of the database table. For example: if the "EventDate" column in the Dinners table is a "datetime", the data model class created by LINQ to SQL will be of type "DateTime" (which is a built-in .NET datatype). This means you will get compile errors if you attempt to assign an integer or boolean to it from code, and it will raise an error automatically if you attempt to implicitly convert a non-valid string type to it at runtime.

LINQ to SQL will also automatically handles escaping SQL values for you when using strings - which helps protect you against SQL injection attacks when using it.

Validation and Business Rule Logic

Schema validation is useful as a first step, but is rarely sufficient. Most real-world scenarios require the ability to specify richer validation logic that can span multiple properties, execute code, and often have awareness of a model's state (for example: is it being created /updated/deleted, or within a domain-specific state like "archived"). There are a variety of different patterns and frameworks that can be used to define and apply validation rules to model classes, and there are several .NET based frameworks out there that can be used to help with this. You can use pretty much any of them within ASP.NET MVC applications.

For the purposes of our NerdDinner application, we'll use a relatively simple and straight-forward pattern where we expose an IsValid property and a GetRuleViolations() method on our Dinner model object. The IsValid property will return true or false depending on whether the validation and business rules are all valid. The GetRuleViolations() method will return a list of any rule errors.

We'll implement IsValid and GetRuleViolations() for our Dinner model by adding a "partial class" to our project.

Partial classes can be used to add methods/properties/events to classes maintained by a VS designer (like the Dinner class generated by the LINQ to SQL designer) and help avoid the tool from messing with our code. We can add a new partial class to our project by right-clicking on the \Models folder, and then select the "Add New Item" menu command. We can then choose the "Class" template within the "Add New Item" dialog and name it Dinner.cs.

Clicking the "Add" button will add a Dinner.cs file to our project and open it within the IDE. We can then implement a basic rule/validation enforcement framework using the below code:

```
public partial class Dinner {

    public bool IsValid {
        get { return (GetRuleViolations().Count() == 0); }
    }

    public IEnumerable<RuleViolation> GetRuleViolations() {
        yield break;
    }

    partial void OnValidate(ChangeAction action) {
        if (!IsValid)
            throw new ApplicationException("Rule violations prevent saving");
    }
}

public class RuleViolation {

    public string ErrorMessage { get; private set; }
    public string PropertyName { get; private set; }

    public RuleViolation(string errorMessage, string propertyName) {
        ErrorMessage = errorMessage;
        PropertyName = propertyName;
    }
}
```

A few notes about the above code:

- The Dinner class is prefaced with a "partial" keyword – which means the code contained within it will be combined with the class generated/maintained by the LINQ to SQL designer and compiled into a single class.
- The RuleViolation class is a helper class we'll add to the project that allows us to provide more details about a rule violation.
- The Dinner.GetRuleViolations() method causes our validation and business rules to be evaluated (we'll implement them shortly). It then returns back a sequence of RuleViolation objects that provide more details

about any rule errors.

- The Dinner.IsValid property provides a convenient helper property that indicates whether the Dinner object has any active RuleViolations. It can be proactively checked by a developer using the Dinner object at anytime (and does not raise an exception).
- The Dinner.OnValidate() partial method is a hook that LINQ to SQL provides that allows us to be notified anytime the Dinner object is about to be persisted within the database. Our OnValidate() implementation above ensures that the Dinner has no RuleViolations before it is saved. If it is in an invalid state it raises an exception, which will cause LINQ to SQL to abort the transaction.

This approach provides a simple framework that we can integrate validation and business rules into. For now let's add the below rules to our GetRuleViolations() method:

```
public IEnumerable<RuleViolation> GetRuleViolations() {

    if (String.IsNullOrEmpty(Title))
        yield return new RuleViolation("Title required","Title");

    if (String.IsNullOrEmpty(Description))
        yield return new RuleViolation("Description required","Description");

    if (String.IsNullOrEmpty(HostedBy))
        yield return new RuleViolation("HostedBy required", "HostedBy");

    if (String.IsNullOrEmpty(Address))
        yield return new RuleViolation("Address required", "Address");

    if (String.IsNullOrEmpty(Country))
        yield return new RuleViolation("Country required", "Country");

    if (String.IsNullOrEmpty(ContactPhone))
        yield return new RuleViolation("Phone# required", "ContactPhone");

    if (!PhoneValidator.IsValidNumber(ContactPhone, Country))
        yield return new RuleViolation("Phone# does not match country", "ContactPhone");

    yield break;
}
```

We are using the "yield return" feature of C# to return a sequence of any RuleViolations. The first six rule checks above simply enforce that string properties on our Dinner cannot be null or empty. The last rule is a little more interesting, and calls a PhoneValidator.IsValidNumber() helper method that we can add to our project to verify that the ContactPhone number format matches the Dinner's country.

We can use .NET's regular expression support to implement this phone validation support. Below is a simple PhoneValidator implementation that we can add to our project that enables us to add country-specific Regex pattern checks:

```
public class PhoneValidator {

    static IDictionary<string, Regex> countryRegex = new Dictionary<string, Regex>() {
           { "USA", new Regex("^[2-9]\\d{2}-\\d{3}-\\d{4}$")},
           { "UK", new Regex("(^1300\\d{6}$)|(^1800|1900|1902\\d{6}$)|(^0[2|3|7|8]{1}[0-9]{8}$)|(^13\\d{4}$)|
(^04\\d{2,3}\\d{6}$)")},
           { "Netherlands", new Regex("(^\\+[0-9]{2}|^\\+[0-9]{2}\\(0\\)|^\\(\\+[0-9]{2}\\)\\(0\\)|^00[0-9]
{2}|^0)([0-9]{9}$|[0-9\\-\\s]{10}$)")},
    };

    public static bool IsValidNumber(string phoneNumber, string country) {

        if (country != null && countryRegex.ContainsKey(country))
            return countryRegex[country].IsMatch(phoneNumber);
        else
            return false;
    }

    public static IEnumerable<string> Countries {
        get {
            return countryRegex.Keys;
        }
    }
}
```

Handling Validation and Business Logic Violations

Now that we've added the above validation and business rule code, any time we try to create or update a Dinner, our validation logic rules will be evaluated and enforced.

Developers can write code like below to proactively determine if a Dinner object is valid, and retrieve a list of all violations in it without raising any exceptions:

```
Dinner dinner = dinnerRepository.GetDinner(5);

dinner.Country = "USA";
dinner.ContactPhone = "425-555-BOGUS";

if (!dinner.IsValid) {

    var errors = dinner.GetRuleViolations();

    // do something to fix the errors
}
```

If we attempt to save a Dinner in an invalid state, an exception will be raised when we call the Save() method on the DinnerRepository. This occurs because LINQ to SQL automatically calls our Dinner.OnValidate() partial method before it saves the Dinner's changes, and we added code to Dinner.OnValidate() to raise an exception if any rule violations exist in the Dinner. We can catch this exception and reactively retrieve a list of the violations to fix:

```
Dinner dinner = dinnerRepository.GetDinner(5);

try {

    dinner.Country = "USA";
    dinner.ContactPhone = "425-555-BOGUS";

    dinnerRepository.Save();
}
catch {

    var errors = dinner.GetRuleViolations();

    // do something to fix errors
}
```

Because our validation and business rules are implemented within our model layer, and not within the UI layer, they will be applied and used across all scenarios within our application. We can later change or add business rules and have all code that works with our Dinner objects honor them.

Having the flexibility to change business rules in one place, without having these changes ripple throughout the application and UI logic, is a sign of a well-written application, and a benefit that an MVC framework helps encourage.

Next Step

We've now got a model that we can use to both query and update our database.

Let's now add some controllers and views to the project that we can use to build an HTML UI experience around it.

Use Controllers and Views to Implement a Listing/Details UI

> This is step 4 of a free "NerdDinner" application tutorial that walks-through how to build a small, but complete, web application using ASP.NET MVC 1.
>
> Step 4 shows how to add a Controller to the application that takes advantage of our model to provide users with a data listing/details navigation experience for dinners on our NerdDinner site.
>
> If you are using ASP.NET MVC 3, we recommend you follow the Getting Started With MVC 3 or MVC Music Store tutorials.

NerdDinner Step 4: Controllers and Views

With traditional web frameworks (classic ASP, PHP, ASP.NET Web Forms, etc), incoming URLs are typically mapped to files on disk. For example: a request for a URL like "/Products.aspx" or "/Products.php" might be processed by a "Products.aspx" or "Products.php" file.

Web-based MVC frameworks map URLs to server code in a slightly different way. Instead of mapping incoming URLs to files, they instead map URLs to methods on classes. These classes are called "Controllers" and they are responsible for processing incoming HTTP requests, handling user input, retrieving and saving data, and determining the response to send back to the client (display HTML, download a file, redirect to a different URL, etc).

Now that we have built up a basic model for our NerdDinner application, our next step will be to add a Controller to the application that takes advantage of it to provide users with a data listing/details navigation experience for Dinners on our site.

Adding a DinnersController Controller

We'll begin by right-clicking on the "Controllers" folder within our web project, and then select the **Add->Controller** menu command (you can also execute this command by typing Ctrl-M, Ctrl-C):

This will bring up the "Add Controller" dialog:

We'll name the new controller "DinnersController" and click the "Add" button. Visual Studio will then add a DinnersController.cs file under our \Controllers directory:

It will also open up the new DinnersController class within the code-editor.

Adding Index() and Details() Action Methods to the DinnersController Class

We want to enable visitors using our application to browse a list of upcoming dinners, and allow them to click on any Dinner in the list to see specific details about it. We'll do this by publishing the following URLs from our

application:

URL	PURPOSE
/Dinners/	Display an HTML list of upcoming dinners
/Dinners/Details/[id]	Display details about a specific dinner indicated by an "id" parameter embedded within the URL – which will match the DinnerID of the dinner in the database. For example: /Dinners/Details/2 would display an HTML page with details about the Dinner whose DinnerID value is 2.

We will publish initial implementations of these URLs by adding two public "action methods" to our DinnersController class like below:

```
public class DinnersController : Controller {

    //
    // HTTP-GET: /Dinners/

    public void Index() {
        Response.Write("<h1>Coming Soon: Dinners</h1>");
    }

    //
    // HTTP-GET: /Dinners/Details/2

    public void Details(int id) {
        Response.Write("<h1>Details DinnerID: " + id + "</h1>");
    }
}
```

We'll then run the NerdDinner application and use our browser to invoke them. Typing in the *"/Dinners/"* URL will cause our *Index()* method to run, and it will send back the following response:

Typing in the *"/Dinners/Details/2"* URL will cause our *Details()* method to run, and send back the following response:

You might be wondering - how did ASP.NET MVC know to create our DinnersController class and invoke those methods? To understand that let's take a quick look at how routing works.

Understanding ASP.NET MVC Routing

ASP.NET MVC includes a powerful URL routing engine that provides a lot of flexibility in controlling how URLs are mapped to controller classes. It allows us to completely customize how ASP.NET MVC chooses which controller class to create, which method to invoke on it, as well as configure different ways that variables can be automatically parsed from the URL/Querystring and passed to the method as parameter arguments. It delivers the flexibility to totally optimize a site for SEO (search engine optimization) as well as publish any URL structure we want from an application.

By default, new ASP.NET MVC projects come with a preconfigured set of URL routing rules already registered. This enables us to easily get started on an application without having to explicitly configure anything. The default routing rule registrations can be found within the "Application" class of our projects – which we can open by double-clicking the "Global.asax" file in the root of our project:

The default ASP.NET MVC routing rules are registered within the "RegisterRoutes" method of this class:

```
public void RegisterRoutes(RouteCollection routes) {

    routes.IgnoreRoute("{resource}.axd/{*pathInfo}");

    routes.MapRoute(
        "Default",                                          // Route name
        "{controller}/{action}/{id}",                       // URL w/ params
        new { controller="Home", action="Index",id="" }  // Param defaults
    );
}
```

The "routes.MapRoute()" method call above registers a default routing rule that maps incoming URLs to controller classes using the URL format: "/{controller}/{action}/{id}" – where "controller" is the name of the controller class to instantiate, "action" is the name of a public method to invoke on it, and "id" is an optional parameter embedded within the URL that can be passed as an argument to the method. The third parameter passed to the "MapRoute()" method call is a set of default values to use for the controller/action/id values in the event that they are not present in the URL (Controller = "Home", Action="Index", Id="").

Below is a table that demonstrates how a variety of URLs are mapped using the default "*/{controllers}/{action}/{id}*" route rule:

URL	CONTROLLER CLASS	ACTION METHOD	PARAMETERS PASSED
/Dinners/Details/2	DinnersController	Details(id)	id=2
/Dinners/Edit/5	DinnersController	Edit(id)	id=5
/Dinners/Create	DinnersController	Create()	N/A
/Dinners	DinnersController	Index()	N/A
/Home	HomeController	Index()	N/A
/	HomeController	Index()	N/A

The last three rows show the default values (Controller = Home, Action = Index, Id = "") being used. Because the "Index" method is registered as the default action name if one isn't specified, the "/Dinners" and "/Home" URLs cause the Index() action method to be invoked on their Controller classes. Because the "Home" controller is registered as the default controller if one isn't specified, the "/" URL causes the HomeController to be created, and the Index() action method on it to be invoked.

If you don't like these default URL routing rules, the good news is that they are easy to change - just edit them within the RegisterRoutes method above. For our NerdDinner application, though, we aren't going to change any of the default URL routing rules – instead we'll just use them as-is.

Using the DinnerRepository from our DinnersController

Let's now replace our current implementation of the DinnersController's Index() and Details() action methods with implementations that use our model.

We'll use the DinnerRepository class we built earlier to implement the behavior. We'll begin by adding a "using" statement that references the "NerdDinner.Models" namespace, and then declare an instance of our DinnerRepository as a field on our DinnerController class.

Later in this chapter we'll introduce the concept of "Dependency Injection" and show another way for our Controllers to obtain a reference to a DinnerRepository that enables better unit testing – but for right now we'll just create an instance of our DinnerRepository inline like below.

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Web;
using System.Web.Mvc;
using NerdDinner.Models;

namespace NerdDinner.Controllers {

    public class DinnersController : Controller {

        DinnerRepository dinnerRepository = new DinnerRepository();

        //
        // GET: /Dinners/

        public void Index() {
            var dinners = dinnerRepository.FindUpcomingDinners().ToList();
        }

        //
        // GET: /Dinners/Details/2

        public void Details(int id) {
            Dinner dinner = dinnerRepository.GetDinner(id);
        }
    }
}
```

Now we are ready to generate a HTML response back using our retrieved data model objects.

Using Views with our Controller

While it is possible to write code within our action methods to assemble HTML and then use the *Response.Write()* helper method to send it back to the client, that approach becomes fairly unwieldy quickly. A much better approach is for us to only perform application and data logic inside our DinnersController action methods, and to then pass the data needed to render a HTML response to a separate "view" template that is responsible for outputting the HTML representation of it. As we'll see in a moment, a "view" template is a text file that typically contains a combination of HTML markup and embedded rendering code.

Separating our controller logic from our view rendering brings several big benefits. In particular it helps enforce a clear "separation of concerns" between the application code and UI formatting/rendering code. This makes it much easier to unit-test application logic in isolation from UI rendering logic. It makes it easier to later modify the UI rendering templates without having to make application code changes. And it can make it easier for developers and designers to collaborate together on projects.

We can update our DinnersController class to indicate that we want to use a view template to send back an HTML UI response by changing the method signatures of our two action methods from having a return type of "void" to instead have a return type of "ActionResult". We can then call the *View()* helper method on the Controller base class to return back a "ViewResult" object like below:

```
public class DinnersController : Controller {

    DinnerRepository dinnerRepository = new DinnerRepository();

    //
    // GET: /Dinners/

    public ActionResult Index() {

        var dinners = dinnerRepository.FindUpcomingDinners().ToList();

        return View("Index", dinners);
    }

    //
    // GET: /Dinners/Details/2

    public ActionResult Details(int id) {

        Dinner dinner = dinnerRepository.GetDinner(id);

        if (dinner == null)
            return View("NotFound");
        else
            return View("Details", dinner);
    }
}
```

The signature of the *View()* helper method we are using above looks like below:

```
ViewResult View(string viewName, object model);
```

The first parameter to the *View()* helper method is the name of the view template file we want to use to render the HTML response. The second parameter is a model object that contains the data that the view template needs in order to render the HTML response.

Within our Index() action method we are calling the *View()* helper method and indicating that we want to render an HTML listing of dinners using an "Index" view template. We are passing the view template a sequence of Dinner objects to generate the list from:

```
//
    // GET: /Dinners/

    public ActionResult Index() {

        var dinners = dinnerRepository.FindUpcomingDinners().ToList();

        return View("Index", dinners);
    }
```

Within our Details() action method we attempt to retrieve a Dinner object using the id provided within the URL. If a valid Dinner is found we call the *View()* helper method, indicating we want to use a "Details" view template to render the retrieved Dinner object. If an invalid dinner is requested, we render a helpful error message that indicates that the Dinner doesn't exist using a "NotFound" view template (and an overloaded version of the *View()* helper method that just takes the template name):

```
//
    // GET: /Dinners/Details/2

    public ActionResult Details(int id) {

        Dinner dinner = dinnerRepository.FindDinner(id);

        if (dinner == null)
            return View("NotFound");
        else
            return View("Details", dinner);
    }
```

Let's now implement the "NotFound", "Details", and "Index" view templates.

Implementing the "NotFound" View Template

We'll begin by implementing the "NotFound" view template – which displays a friendly error message indicating that the requested dinner can't be found.

We'll create a new view template by positioning our text cursor within a controller action method, and then right click and choose the "Add View" menu command (we can also execute this command by typing Ctrl-M, Ctrl-V):

This will bring up an "Add View" dialog like below. By default the dialog will pre-populate the name of the view to create to match the name of the action method the cursor was in when the dialog was launched (in this case "Details"). Because we want to first implement the "NotFound" template, we'll override this view name and set it to instead be "NotFound":

When we click the "Add" button, Visual Studio will create a new "NotFound.aspx" view template for us within the "\Views\Dinners" directory (which it will also create if the directory doesn't already exist):

It will also open up our new "NotFound.aspx" view template within the code-editor:

View templates by default have two "content regions" where we can add content and code. The first allows us to customize the "title" of the HTML page sent back. The second allows us to customize the "main content" of the HTML page sent back.

To implement our "NotFound" view template we'll add some basic content:

```
<asp:Content ID="Title" ContentPlaceHolderID="TitleContent" runat="server">
    Dinner Not Found
</asp:Content>

<asp:Content ID="Main" ContentPlaceHolderID="MainContent" runat="server">

    <h2>Dinner Not Found</h2>

    <p>Sorry - but the dinner you requested doesn't exist or was deleted.</p>

</asp:Content>
```

We can then try it out within the browser. To do this let's request the *"/Dinners/Details/9999"* URL. This will refer to a dinner that doesn't currently exist in the database, and will cause our DinnersController.Details() action method to render our "NotFound" view template:

One thing you'll notice in the screen-shot above is that our basic view template has inherited a bunch of HTML that surrounds the main content on the screen. This is because our view-template is using a "master page"

template that enables us to apply a consistent layout across all views on the site. We'll discuss how master pages work more in a later part of this tutorial.

Implementing the "Details" View Template

Let's now implement the "Details" view template – which will generate HTML for a single Dinner model.

We'll do this by positioning our text cursor within the Details action method, and then right click and choose the "Add View" menu command (or press Ctrl-M, Ctrl-V):

This will bring up the "Add View" dialog. We'll keep the default view name ("Details"). We'll also select the "Create a strongly-typed View" checkbox in the dialog and select (using the combobox dropdown) the name of the model type we are passing from the Controller to the View. For this view we are passing a Dinner object (the fully qualified name for this type is: "NerdDinner.Models.Dinner"):

Unlike the previous template, where we chose to create an "Empty View", this time we will choose to automatically "scaffold" the view using a "Details" template. We can indicate this by changing the "View content" drop-down in the dialog above.

"Scaffolding" will generate an initial implementation of our details view template based on the Dinner object we are passing to it. This provides an easy way for us to quickly get started on our view template implementation.

When we click the "Add" button, Visual Studio will create a new "Details.aspx" view template file for us within our "\Views\Dinners" directory:

It will also open up our new "Details.aspx" view template within the code-editor. It will contain an initial scaffold implementation of a details view based on a Dinner model. The scaffolding engine uses .NET reflection to look at the public properties exposed on the class passed it, and will add appropriate content based on each type it finds:

```
<asp:Content ID="Title" ContentPlaceHolderID="TitleContent" runat="server">
    Details
</asp:Content>

<asp:Content ID="Main" ContentPlaceHolderID="MainContent" runat="server">

    <h2>Details</h2>

    <fieldset>
        <legend>Fields</legend>
        <p>
            DinnerID:
            <%=Html.Encode(Model.DinnerID) %>
        </p>
        <p>
            Title:
            <%=Html.Encode(Model.Title) %>
        </p>
        <p>
            EventDate:
            <%= Html.Encode(String.Format("{0:g}", Model.EventDate)) %>
        </p>
        <p>
            Description:
            <%=Html.Encode(Model.Description) %>
        </p>
        <p>
            HostedBy:
            <%=Html.Encode(Model.HostedBy) %>
        </p>
        <p>
            ContactPhone:
            <%=Html.Encode(Model.ContactPhone) %>
        </p>
        <p>
            Address:
            <%=Html.Encode(Model.Address) %>
        </p>
        <p>
            Country:
            <%=Html.Encode(Model.Country) %>
        </p>
        <p>
            Latitude:
            <%= Html.Encode(String.Format("{0:F}",Model.Latitude)) %>
        </p>
        <p>
            Longitude:
            <%= Html.Encode(String.Format("{0:F}",Model.Longitude)) %>
        </p>
    </fieldset>

    <p>
        <%=Html.ActionLink("Edit","Edit", new { id=Model.DinnerID }) %>|
        <%=Html.ActionLink("Back to List", "Index") %>
    </p>

</asp:Content>
```

We can request the *"/Dinners/Details/1"* URL to see what this "details" scaffold implementation looks like in the browser. Using this URL will display one of the dinners we manually added to our database when we first created it:

This gets us up and running quickly, and provides us with an initial implementation of our Details.aspx view. We can then go and tweak it to customize the UI to our satisfaction.

When we look at the Details.aspx template more closely, we'll find that it contains static HTML as well as embedded rendering code. <% %> code nuggets execute code when the view template renders, and <%= %> code nuggets execute the code contained within them and then render the result to the output stream of the template.

We can write code within our View that accesses the "Dinner" model object that was passed from our controller using a strongly-typed "Model" property. Visual Studio provides us with full code-intellisense when accessing this "Model" property within the editor:

Let's make some tweaks so that the source for our final Details view template looks like below:

```
<asp:Content ID="Title" ContentPlaceHolderID="TitleContent" runat="server">
    Dinner: <%=Html.Encode(Model.Title) %>
</asp:Content>

<asp:Content ID="Main" ContentPlaceHolderID="MainContent" runat="server">

    <h2><%=Html.Encode(Model.Title) %></h2>
    <p>
        <strong>When:</strong>
        <%=Model.EventDate.ToShortDateString() %>

        <strong>@</strong>
        <%=Model.EventDate.ToShortTimeString() %>
    </p>
    <p>
        <strong>Where:</strong>
        <%=Html.Encode(Model.Address) %>,
        <%=Html.Encode(Model.Country) %>
    </p>
     <p>
        <strong>Description:</strong>
        <%=Html.Encode(Model.Description) %>
    </p>
    <p>
        <strong>Organizer:</strong>
        <%=Html.Encode(Model.HostedBy) %>
        (<%=Html.Encode(Model.ContactPhone) %>)
    </p>

    <%= Html.ActionLink("Edit Dinner", "Edit", new { id=Model.DinnerID })%> |
    <%= Html.ActionLink("Delete Dinner","Delete", new { id=Model.DinnerID})%>

</asp:Content>
```

When we access the *"/Dinners/Details/1"* URL again it will now render like below:

Implementing the "Index" View Template

Let's now implement the "Index" view template – which will generate a listing of upcoming Dinners. To-do this we'll position our text cursor within the Index action method, and then right click and choose the "Add View" menu command (or press Ctrl-M, Ctrl-V).

Within the "Add View" dialog we'll keep the view template named "Index" and select the "Create a strongly-typed view" checkbox. This time we will choose to automatically generate a "List" view template, and select "NerdDinner.Models.Dinner" as the model type passed to the view (which because we have indicated we are creating a "List" scaffold will cause the Add View dialog to assume we are passing a sequence of Dinner objects from our Controller to the View):

When we click the "Add" button, Visual Studio will create a new "Index.aspx" view template file for us within our "\Views\Dinners" directory. It will "scaffold" an initial implementation within it that provides an HTML table listing of the Dinners we pass to the view.

When we run the application and access the *"/Dinners/"* URL it will render our list of dinners like so:

The table solution above gives us a grid-like layout of our Dinner data – which isn't quite what we want for our consumer facing Dinner listing. We can update the Index.aspx view template and modify it to list fewer columns of data, and use a <ul> element to render them instead of a table using the code below:

```
<asp:Content ID="Main" ContentPlaceHolderID="MainContent" runat="server">

    <h2>Upcoming Dinners</h2>

    <ul>
        <% foreach (var dinner in Model) { %>

            <li>
                <%=Html.Encode(dinner.Title) %>
                on
                <%=Html.Encode(dinner.EventDate.ToShortDateString())%>
                @
                <%=Html.Encode(dinner.EventDate.ToShortTimeString())%>
            </li>

        <% } %>
    </ul>

</asp:Content>
```

We are using the "var" keyword within the above foreach statement as we loop over each dinner in our Model. Those unfamiliar with C# 3.0 might think that using "var" means that the dinner object is late-bound. It instead means that the compiler is using type-inference against the strongly typed "Model" property (which is of type "IEnumerable<Dinner>") and compiling the local "dinner" variable as a Dinner type – which means we get full intellisense and compile-time checking for it within code blocks:

```
<ul>
    <% foreach (var dinner in Model) { %>

        <li>
            <%= Html.Encode(dinner. %>
```

When we hit refresh on the */Dinners* URL in our browser our updated view now looks like below:

This is looking better – but isn't entirely there yet. Our last step is to enable end-users to click individual Dinners in the list and see details about them. We'll implement this by rendering HTML hyperlink elements that link to the Details action method on our DinnersController.

We can generate these hyperlinks within our Index view in one of two ways. The first is to manually create HTML <a> elements like below, where we embed <% %> blocks within the <a> HTML element:

```
<% foreach (var dinner in Model) { %>

    <li>
        <a href="/Dinners/Details/<%=dinner.DinnerID %>">
            <%= Html.Encode(dinner.Title) %>
        </a>
        on
        <%= Html.Encode(dinner.EventDate.ToShortDateString()) %>
        @
        <%= Html.Encode(dinner.EventDate.ToShortTimeString()) %>
    </li>

<% } %>
```

An alternative approach we can use is to take advantage of the built-in "Html.ActionLink()" helper method within ASP.NET MVC that supports programmatically creating an HTML <a> element that links to another action method

on a Controller:

```
<%= Html.ActionLink(dinner.Title, "Details", new { id=dinner.DinnerID }) %>
```

The first parameter to the Html.ActionLink() helper method is the link-text to display (in this case the title of the dinner), the second parameter is the Controller action name we want to generate the link to (in this case the Details method), and the third parameter is a set of parameters to send to the action (implemented as an anonymous type with property name/values). In this case we are specifying the "id" parameter of the dinner we want to link to, and because the default URL routing rule in ASP.NET MVC is "{Controller}/{Action}/{id}" the Html.ActionLink() helper method will generate the following output:

```
<a href="/Dinners/Details/1">.NET Futures</a>
```

For our Index.aspx view we'll use the Html.ActionLink() helper method approach and have each dinner in the list link to the appropriate details URL:

```
<asp:Content ID="Title" ContentPlaceHolderID="TitleContent" runat="server">
    Upcoming Dinners
</asp:Content>

<asp:Content ID="Main" ContentPlaceHolderID="MainContent" runat="server">

    <h2>Upcoming Dinners</h2>

    <ul>
        <% foreach (var dinner in Model) { %>

            <li>
                <%=Html.ActionLink(dinner.Title, "Details", new { id=dinner.DinnerID }) %>
                on
                <%=Html.Encode(dinner.EventDate.ToShortDateString())%>
                @
                <%=Html.Encode(dinner.EventDate.ToShortTimeString())%>
            </li>

        <% } %>
    </ul>
</asp:Content>
```

And now when we hit the */Dinners* URL our dinner list looks like below:

When we click any of the Dinners in the list we'll navigate to see details about it:

Convention-based naming and the \Views directory structure

ASP.NET MVC applications by default use a convention-based directory naming structure when resolving view templates. This allows developers to avoid having to fully-qualify a location path when referencing views from within a Controller class. By default ASP.NET MVC will look for the view template file within the *\Views[ControllerName]* directory underneath the application.

For example, we've been working on the DinnersController class – which explicitly references three view templates: "Index", "Details" and "NotFound". ASP.NET MVC will by default look for these views within the

Views\Dinners directory underneath our application root directory:

Notice above how there are currently three controller classes within the project (DinnersController, HomeController and AccountController – the last two were added by default when we created the project), and there are three sub-directories (one for each controller) within the \Views directory.

Views referenced from the Home and Accounts controllers will automatically resolve their view templates from the respective *\Views\Home* and *\Views\Account* directories. The *\Views\Shared* sub-directory provides a way to store view templates that are re-used across multiple controllers within the application. When ASP.NET MVC attempts to resolve a view template, it will first check within the *\Views[Controller]* specific directory, and if it can't find the view template there it will look within the *\Views\Shared* directory.

When it comes to naming individual view templates, the recommended guidance is to have the view template share the same name as the action method that caused it to render. For example, above our "Index" action method is using the "Index" view to render the view result, and the "Details" action method is using the "Details" view to render its results. This makes it easy to quickly see which template is associated with each action.

Developers do not need to explicitly specify the view template name when the view template has the same name as the action method being invoked on the controller. We can instead just pass the model object to the "View()" helper method (without specifying the view name), and ASP.NET MVC will automatically infer that we want to use the *\Views[ControllerName][ActionName]* view template on disk to render it.

This allows us to clean up our controller code a little, and avoid duplicating the name twice in our code:

```
public class DinnersController : Controller {

    DinnerRepository dinnerRepository = new DinnerRepository();

    //
    // GET: /Dinners/

    public ActionResult Index() {

        var dinners = dinnerRepository.FindUpcomingDinners().ToList();

        return View(dinners);
    }

    //
    // GET: /Dinners/Details/2

    public ActionResult Details(int id) {

        Dinner dinner = dinnerRepository.GetDinner(id);

        if (dinner == null)
            return View("NotFound");
        else
            return View(dinner);
    }
}
```

The above code is all that is needed to implement a nice Dinner listing/details experience for the site.

Next Step

We now have a nice Dinner browsing experience built.

Let's now enable CRUD (Create, Read, Update, Delete) data form editing support.

> This is step 5 of a free "NerdDinner" application tutorial that walks-through how to build a small, but complete, web application using ASP.NET MVC 1.
>
> Step 5 shows how to take our DinnersController class further by enable support for editing, creating and deleting Dinners with it as well.
>
> If you are using ASP.NET MVC 3, we recommend you follow the Getting Started With MVC 3 or MVC Music Store tutorials.

NerdDinner Step 5: Create, Update, Delete Form Scenarios

We've introduced controllers and views, and covered how to use them to implement a listing/details experience for Dinners on site. Our next step will be to take our DinnersController class further and enable support for editing, creating and deleting Dinners with it as well.

URLs handled by DinnersController

We previously added action methods to DinnersController that implemented support for two URLs: */Dinners* and */Dinners/Details/[id]*.

URL	VERB	PURPOSE
/Dinners/	GET	Display an HTML list of upcoming dinners.
/Dinners/Details/[id]	GET	Display details about a specific dinner.

We will now add action methods to implement three additional URLs: */Dinners/Edit/[id]*, */Dinners/Create*, and */Dinners/Delete/[id]*. These URLs will enable support for editing existing Dinners, creating new Dinners, and deleting Dinners.

We will support both HTTP GET and HTTP POST verb interactions with these new URLs. HTTP GET requests to these URLs will display the initial HTML view of the data (a form populated with the Dinner data in the case of "edit", a blank form in the case of "create", and a delete confirmation screen in the case of "delete"). HTTP POST requests to these URLs will save/update/delete the Dinner data in our DinnerRepository (and from there to the database).

URL	VERB	PURPOSE
/Dinners/Edit/[id]	GET	Display an editable HTML form populated with Dinner data.

URL	VERB	PURPOSE
POST	Save the form changes for a particular Dinner to the database.	
/Dinners/Create	GET	Display an empty HTML form that allows users to define new Dinners.
POST	Create a new Dinner and save it in the database.	
/Dinners/Delete/[id]	GET	Display delete confirmation screen.
POST	Deletes the specified dinner from the database.	

Edit Support

Let's begin by implementing the "edit" scenario.

The HTTP-GET Edit Action Method

We'll start by implementing the HTTP "GET" behavior of our edit action method. This method will be invoked when the */Dinners/Edit/[id]* URL is requested. Our implementation will look like:

```
//
// GET: /Dinners/Edit/2

public ActionResult Edit(int id) {

    Dinner dinner = dinnerRepository.GetDinner(id);

    return View(dinner);
}
```

The code above uses the DinnerRepository to retrieve a Dinner object. It then renders a View template using the Dinner object. Because we haven't explicitly passed a template name to the *View()* helper method, it will use the convention based default path to resolve the view template: /Views/Dinners/Edit.aspx.

Let's now create this view template. We will do this by right-clicking within the Edit method and selecting the "Add View" context menu command:

Within the "Add View" dialog we'll indicate that we are passing a Dinner object to our view template as its model, and choose to auto-scaffold an "Edit" template:

When we click the "Add" button, Visual Studio will add a new "Edit.aspx" view template file for us within the "\Views\Dinners" directory. It will also open up the new "Edit.aspx" view template within the code-editor – populated with an initial "Edit" scaffold implementation like below:

Let's make a few changes to the default "edit" scaffold generated, and update the edit view template to have the content below (which removes a few of the properties we don't want to expose):

```
<asp:Content ID="Title" ContentPlaceHolderID="TitleContent" runat="server">
    Edit: <%=Html.Encode(Model.Title)%>
</asp:Content>

<asp:Content ID="Main" ContentPlaceHolderID="MainContent" runat="server">

    <h2>Edit Dinner</h2>

    <%=Html.ValidationSummary("Please correct the errors and try again.") %>

    <% using (Html.BeginForm()) { %>

        <fieldset>
            <p>
                <label for="Title">Dinner Title:</label>
                <%=Html.TextBox("Title") %>
                <%=Html.ValidationMessage("Title", "*") %>
            </p>
            <p>
                <label for="EventDate">EventDate:</label>
                <%=Html.TextBox("EventDate", String.Format("{0:g}", Model.EventDate))%>
                <%=Html.ValidationMessage("EventDate", "*") %>
            </p>
            <p>
                <label for="Description">Description:</label>
                <%=Html.TextArea("Description") %>
                <%=Html.ValidationMessage("Description", "*")%>
            </p>
            <p>
                <label for="Address">Address:</label>
                <%=Html.TextBox("Address") %>
                <%=Html.ValidationMessage("Address", "*") %>
            </p>
            <p>
                <label for="Country">Country:</label>
                <%=Html.TextBox("Country") %>
                <%=Html.ValidationMessage("Country", "*") %>
            </p>
            <p>
                <label for="ContactPhone">ContactPhone #:</label>
                <%=Html.TextBox("ContactPhone") %>
                <%=Html.ValidationMessage("ContactPhone", "*") %>
            </p>
            <p>
                <label for="Latitude">Latitude:</label>
                <%=Html.TextBox("Latitude") %>
                <%=Html.ValidationMessage("Latitude", "*") %>
            </p>
            <p>
                <label for="Longitude">Longitude:</label>
                <%=Html.TextBox("Longitude") %>
                <%=Html.ValidationMessage("Longitude", "*") %>
            </p>
            <p>
                <input type="submit" value="Save"/>
            </p>
        </fieldset>

    <% } %>

</asp:Content>
```

When we run the application and request the *"/Dinners/Edit/1"* URL we will see the following page:

The HTML markup generated by our view looks like below. It is standard HTML – with a <form> element that performs an HTTP POST to the */Dinners/Edit/1* URL when the "Save" <input type="submit"/> button is pushed. A HTML <input type="text"/> element has been output for each editable property:

```
<form action="/Dinners/Edit/1" method="post">

    <fieldset>
        <p>
            <label for="Title">Dinner Title:</label>
            <input id="Title" name="Title" type="text" value=".NET Futures" />
        </p>
        <p>
            <label for="EventDate">Event Date:</label>
            <input id="EventDate" name="EventDate" type="text" value="12/6/2009 5:00 PM" />
        </p>

        <!-- Some Fields Omitted for Brevity -->

        <p>
            <input type="submit" value="Save" />
        </p>
    </fieldset>

</form>
```

Html.BeginForm() and Html.TextBox() Html Helper Methods

Our "Edit.aspx" view template is using several "Html Helper" methods: Html.ValidationSummary(), Html.BeginForm(), Html.TextBox(), and Html.ValidationMessage(). In addition to generating HTML markup for us, these helper methods provide built-in error handling and validation support.

Html.BeginForm() helper method

The Html.BeginForm() helper method is what output the HTML <form> element in our markup. In our Edit.aspx view template you'll notice that we are applying a C# "using" statement when using this method. The open curly brace indicates the beginning of the <form> content, and the closing curly brace is what indicates the end of the </form> element:

```
<% using (Html.BeginForm()) { %>

   <fieldset>

      <!-- Fields Omitted for Brevity -->

      <p>
         <input type="submit" value="Save"/>
      </p>
   </fieldset>

<% } %>
```

Alternatively, if you find the "using" statement approach unnatural for a scenario like this, you can use a Html.BeginForm() and Html.EndForm() combination (which does the same thing):

```
<% Html.BeginForm();  %>

   <fieldset>

      <!-- Fields Omitted for Brevity -->

      <p>
          <input type="submit" value="Save"/>
      </p>
   </fieldset>

<% Html.EndForm(); %>
```

Calling Html.BeginForm() without any parameters will cause it to output a form element that does an HTTP-POST to the current request's URL. That is why our Edit view generates a *<form action="/Dinners/Edit/1"*

method="post"> element. We could have alternatively passed explicit parameters to Html.BeginForm() if we wanted to post to a different URL.

Html.TextBox() helper method

Our Edit.aspx view uses the Html.TextBox() helper method to output <input type="text"/> elements:

```
<%= Html.TextBox("Title") %>
```

The Html.TextBox() method above takes a single parameter – which is being used to specify both the id/name attributes of the <input type="text"/> element to output, as well as the model property to populate the textbox value from. For example, the Dinner object we passed to the Edit view had a "Title" property value of ".NET Futures", and so our Html.TextBox("Title") method call output: *<input id="Title" name="Title" type="text" value=".NET Futures" />*.

Alternatively, we can use the first Html.TextBox() parameter to specify the id/name of the element, and then explicitly pass in the value to use as a second parameter:

```
<%= Html.TextBox("Title", Model.Title)%>
```

Often we'll want to perform custom formatting on the value that is output. The String.Format() static method built-into .NET is useful for these scenarios. Our Edit.aspx view template is using this to format the EventDate value (which is of type DateTime) so that it doesn't show seconds for the time:

```
<%= Html.TextBox("EventDate", String.Format("{0:g}", Model.EventDate)) %>
```

A third parameter to Html.TextBox() can optionally be used to output additional HTML attributes. The code-snippet below demonstrates how to render an additional size="30" attribute and a class="mycssclass" attribute on the <input type="text"/> element. Note how we are escaping the name of the class attribute using a "@" character because "class" is a reserved keyword in C#:

```
<%= Html.TextBox("Title", Model.Title, new { size=30, @class="myclass" } )%>
```

Implementing the HTTP-POST Edit Action Method

We now have the HTTP-GET version of our Edit action method implemented. When a user requests the */Dinners/Edit/1* URL they receive an HTML page like the following:

Pressing the "Save" button causes a form post to the */Dinners/Edit/1* URL, and submits the HTML <input> form values using the HTTP POST verb. Let's now implement the HTTP POST behavior of our edit action method – which will handle saving the Dinner.

We'll begin by adding an overloaded "Edit" action method to our DinnersController that has an "AcceptVerbs" attribute on it that indicates it handles HTTP POST scenarios:

```
//
// POST: /Dinners/Edit/2

[AcceptVerbs(HttpVerbs.Post)]
public ActionResult Edit(int id, FormCollection formValues) {
   ...
}
```

When the [AcceptVerbs] attribute is applied to overloaded action methods, ASP.NET MVC automatically handles dispatching requests to the appropriate action method depending on the incoming HTTP verb. HTTP POST requests to */Dinners/Edit/[id]* URLs will go to the above Edit method, while all other HTTP verb requests to

/Dinners/Edit/[id] URLs will go to the first Edit method we implemented (which did not have an `[AcceptVerbs]` attribute).

SIDE TOPIC: WHY DIFFERENTIATE VIA HTTP VERBS?

You might ask – why are we using a single URL and differentiating its behavior via the HTTP verb? Why not just have two separate URLs to handle loading and saving edit changes? For example: /Dinners/Edit/[id] to display the initial form and /Dinners/Save/[id] to handle the form post to save it? The downside with publishing two separate URLs is that in cases where we post to /Dinners/Save/2, and then need to redisplay the HTML form because of an input error, the end-user will end up having the /Dinners/Save/2 URL in their browser's address bar (since that was the URL the form posted to). If the end-user bookmarks this redisplayed page to their browser favorites list, or copy/pastes the URL and emails it to a friend, they will end up saving a URL that won't work in the future (since that URL depends on post values). By exposing a single URL (like: /Dinners/Edit/[id]) and differentiating the processing of it by HTTP verb, it is safe for end-users to bookmark the edit page and/or send the URL to others.

Retrieving Form Post Values

There are a variety of ways we can access posted form parameters within our HTTP POST "Edit" method. One simple approach is to just use the Request property on the Controller base class to access the form collection and retrieve the posted values directly:

```
//
// POST: /Dinners/Edit/2

[AcceptVerbs(HttpVerbs.Post)]
public ActionResult Edit(int id, FormCollection formValues) {

    // Retrieve existing dinner
    Dinner dinner = dinnerRepository.GetDinner(id);

    // Update dinner with form posted values
    dinner.Title = Request.Form["Title"];
    dinner.Description = Request.Form["Description"];
    dinner.EventDate = DateTime.Parse(Request.Form["EventDate"]);
    dinner.Address = Request.Form["Address"];
    dinner.Country = Request.Form["Country"];
    dinner.ContactPhone = Request.Form["ContactPhone"];

    // Persist changes back to database
    dinnerRepository.Save();

    // Perform HTTP redirect to details page for the saved Dinner
    return RedirectToAction("Details", new { id = dinner.DinnerID });
}
```

The above approach is a little verbose, though, especially once we add error handling logic.

A better approach for this scenario is to leverage the built-in *UpdateModel()* helper method on the Controller base class. It supports updating the properties of an object we pass it using the incoming form parameters. It uses reflection to determine the property names on the object, and then automatically converts and assigns values to them based on the input values submitted by the client.

We could use the UpdateModel() method to simplify our HTTP-POST Edit Action using this code:

```
//
// POST: /Dinners/Edit/2

[AcceptVerbs(HttpVerbs.Post)]
public ActionResult Edit(int id, FormCollection formValues) {

    Dinner dinner = dinnerRepository.GetDinner(id);

    UpdateModel(dinner);

    dinnerRepository.Save();

    return RedirectToAction("Details", new { id = dinner.DinnerID });
}
```

We can now visit the */Dinners/Edit/1* URL, and change the title of our Dinner:

When we click the "Save" button, we'll perform a form post to our Edit action, and the updated values will be persisted in the database. We will then be redirected to the Details URL for the Dinner (which will display the newly saved values):

Handling Edit Errors

Our current HTTP-POST implementation works fine – except when there are errors.

When a user makes a mistake editing a form, we need to make sure that the form is redisplayed with an informative error message that guides them to fix it. This includes cases where an end-user posts incorrect input (for example: a malformed date string), as well as cases where the input format is valid but there is a business rule violation. When errors occur the form should preserve the input data the user originally entered so that they don't have to refill their changes manually. This process should repeat as many times as necessary until the form successfully completes.

ASP.NET MVC includes some nice built-in features that make error handling and form redisplay easy. To see these features in action let's update our Edit action method with the following code:

```
//
// POST: /Dinners/Edit/2

[AcceptVerbs(HttpVerbs.Post)]
public ActionResult Edit(int id, FormCollection formValues) {

    Dinner dinner = dinnerRepository.GetDinner(id);

    try {

        UpdateModel(dinner);

        dinnerRepository.Save();

        return RedirectToAction("Details", new { id=dinner.DinnerID });
    }
    catch {

        foreach (var issue in dinner.GetRuleViolations()) {
            ModelState.AddModelError(issue.PropertyName, issue.ErrorMessage);
        }

        return View(dinner);
    }
}
```

The above code is similar to our previous implementation – except that we are now wrapping a try/catch error handling block around our work. If an exception occurs either when calling UpdateModel(), or when we try and save the DinnerRepository (which will raise an exception if the Dinner object we are trying to save is invalid because of a rule violation within our model), our catch error handling block will execute. Within it we loop over any rule violations that exist in the Dinner object and add them to a ModelState object (which we'll discuss shortly). We then redisplay the view.

To see this working let's re-run the application, edit a Dinner, and change it to have an empty Title, an EventDate of "BOGUS", and use a UK phone number with a country value of USA. When we press the "Save" button our HTTP POST Edit method will not be able to save the Dinner (because there are errors) and will redisplay the form:

Our application has a decent error experience. The text elements with the invalid input are highlighted in red, and validation error messages are displayed to the end user about them. The form is also preserving the input data the user originally entered – so that they don't have to refill anything.

How, you might ask, did this occur? How did the Title, EventDate, and ContactPhone textboxes highlight themselves in red and know to output the originally entered user values? And how did error messages get displayed in the list at the top? The good news is that this didn't occur by magic - rather it was because we used some of the built-in ASP.NET MVC features that make input validation and error handling scenarios easy.

Understanding ModelState and the Validation HTML Helper Methods

Controller classes have a "ModelState" property collection which provides a way to indicate that errors exist with a model object being passed to a View. Error entries within the ModelState collection identify the name of the model property with the issue (for example: "Title", "EventDate", or "ContactPhone"), and allow a human-friendly error message to be specified (for example: "Title is required").

The *UpdateModel()* helper method automatically populates the ModelState collection when it encounters errors while trying to assign form values to properties on the model object. For example, our Dinner object's EventDate property is of type DateTime. When the UpdateModel() method was unable to assign the string value "BOGUS" to it in the scenario above, the UpdateModel() method added an entry to the ModelState collection indicating an assignment error had occurred with that property.

Developers can also write code to explicitly add error entries into the ModelState collection like we are doing below within our "catch" error handling block, which is populating the ModelState collection with entries based on the active Rule Violations in the Dinner object:

```
[AcceptVerbs(HttpVerbs.Post)]
public ActionResult Edit(int id, FormCollection formValues) {

    Dinner dinner = dinnerRepository.GetDinner(id);

    try {

        UpdateModel(dinner);

        dinnerRepository.Save();

        return RedirectToAction("Details", new { id=dinner.DinnerID });
    }
    catch {

        foreach (var issue in dinner.GetRuleViolations()) {
            ModelState.AddModelError(issue.PropertyName, issue.ErrorMessage);
        }

        return View(dinner);
    }
}
```

Html Helper Integration with ModelState

HTML helper methods - like Html.TextBox() - check the ModelState collection when rendering output. If an error for the item exists, they render the user-entered value and a CSS error class.

For example, in our "Edit" view we are using the Html.TextBox() helper method to render the EventDate of our Dinner object:

```
<%= Html.TextBox("EventDate", String.Format("{0:g}", Model.EventDate)) %>
```

When the view was rendered in the error scenario, the Html.TextBox() method checked the ModelState collection to see if there were any errors associated with the "EventDate" property of our Dinner object. When it determined that there was an error it rendered the submitted user input ("BOGUS") as the value, and added a css error class to the <input type="textbox"/> markup it generated:

```
<input class="input-validation-error"id="EventDate" name="EventDate" type="text" value="BOGUS"/>
```

You can customize the appearance of the css error class to look however you want. The default CSS error class – "input-validation-error" – is defined in the *\content\site.css* stylesheet and looks like below:

```
.input-validation-error
{
    border: 1px solid #ff0000;
    background-color: #ffeeee;
}
```

This CSS rule is what caused our invalid input elements to be highlighted like below:

Html.ValidationMessage() Helper Method

The Html.ValidationMessage() helper method can be used to output the ModelState error message associated with a particular model property:

```
<%= Html.ValidationMessage("EventDate")%>
```

The above code outputs: * The value 'BOGUS' is invalid*

The Html.ValidationMessage() helper method also supports a second parameter that allows developers to override the error text message that is displayed:

```
<%= Html.ValidationMessage("EventDate","*") %>
```

The above code outputs: *** instead of the default error text when an error is present for the EventDate property.

Html.ValidationSummary() Helper Method

The Html.ValidationSummary() helper method can be used to render a summary error message, accompanied by a list of all detailed error messages in the ModelState collection:

The Html.ValidationSummary() helper method takes an optional string parameter – which defines a summary error message to display above the list of detailed errors:

```
<%= Html.ValidationSummary("Please correct the errors and try again.") %>
```

You can optionally use CSS to override what the error list looks like.

Using a AddRuleViolations Helper Method

Our initial HTTP-POST Edit implementation used a foreach statement within its catch block to loop over the Dinner object's Rule Violations and add them to the controller's ModelState collection:

```
catch {
        foreach (var issue in dinner.GetRuleViolations()) {
            ModelState.AddModelError(issue.PropertyName, issue.ErrorMessage);
        }

        return View(dinner);
    }
```

We can make this code a little cleaner by adding a "ControllerHelpers" class to the NerdDinner project, and implement an "AddRuleViolations" extension method within it that adds a helper method to the ASP.NET MVC ModelStateDictionary class. This extension method can encapsulate the logic necessary to populate the ModelStateDictionary with a list of RuleViolation errors:

```
public static class ControllerHelpers {

   public static void AddRuleViolations(this ModelStateDictionary modelState, IEnumerable<RuleViolation>
errors) {

       foreach (RuleViolation issue in errors) {
           modelState.AddModelError(issue.PropertyName, issue.ErrorMessage);
       }
   }
}
```

We can then update our HTTP-POST Edit action method to use this extension method to populate the ModelState collection with our Dinner Rule Violations.

Complete Edit Action Method Implementations

The code below implements all of the controller logic necessary for our Edit scenario:

```
//
// GET: /Dinners/Edit/2

public ActionResult Edit(int id) {

    Dinner dinner = dinnerRepository.GetDinner(id);

    return View(dinner);
}

//
// POST: /Dinners/Edit/2

[AcceptVerbs(HttpVerbs.Post)]
public ActionResult Edit(int id, FormCollection formValues) {

    Dinner dinner = dinnerRepository.GetDinner(id);

    try {

        UpdateModel(dinner);

        dinnerRepository.Save();

        return RedirectToAction("Details", new { id=dinner.DinnerID });
    }
    catch {

        ModelState.AddRuleViolations(dinner.GetRuleViolations());

        return View(dinner);
    }
}
```

The nice thing about our Edit implementation is that neither our Controller class nor our View template has to know anything about the specific validation or business rules being enforced by our Dinner model. We can add additional rules to our model in the future and do not have to make any code changes to our controller or view in order for them to be supported. This provides us with the flexibility to easily evolve our application requirements in the future with a minimum of code changes.

Create Support

We've finished implementing the "Edit" behavior of our DinnersController class. Let's now move on to implement the "Create" support on it – which will enable users to add new Dinners.

The HTTP-GET Create Action Method

We'll begin by implementing the HTTP "GET" behavior of our create action method. This method will be called when someone visits the */Dinners/Create* URL. Our implementation looks like:

```
//
// GET: /Dinners/Create

public ActionResult Create() {

    Dinner dinner = new Dinner() {
        EventDate = DateTime.Now.AddDays(7)
    };

    return View(dinner);
}
```

The code above creates a new Dinner object, and assigns its EventDate property to be one week in the future. It then renders a View that is based on the new Dinner object. Because we haven't explicitly passed a name to the

View() helper method, it will use the convention based default path to resolve the view template: /Views/Dinners/Create.aspx.

Let's now create this view template. We can do this by right-clicking within the Create action method and selecting the "Add View" context menu command. Within the "Add View" dialog we'll indicate that we are passing a Dinner object to the view template, and choose to auto-scaffold a "Create" template:

When we click the "Add" button, Visual Studio will save a new scaffold-based "Create.aspx" view to the "\Views\Dinners" directory, and open it up within the IDE:

Let's make a few changes to the default "create" scaffold file that was generated for us, and modify it up to look like below:

```
<asp:Content ID="Title" ContentPlaceHolderID="TitleContent" runat="server">
     Host a Dinner
</asp:Content>

<asp:Content ID="Main" ContentPlaceHolderID="MainContent" runat="server">

    <h2>Host a Dinner</h2>

    <%=Html.ValidationSummary("Please correct the errors and try again.") %>

    <% using (Html.BeginForm()) {%>

        <fieldset>
            <p>
                <label for="Title">Title:</label>
                <%= Html.TextBox("Title") %>
                <%= Html.ValidationMessage("Title", "*") %>
            </p>
            <p>
                <label for="EventDate">EventDate:</label>
                <%=Html.TextBox("EventDate") %>
                <%=Html.ValidationMessage("EventDate", "*") %>
            </p>
            <p>
                <label for="Description">Description:</label>
                <%=Html.TextArea("Description") %>
                <%=Html.ValidationMessage("Description", "*") %>
            </p>
            <p>
                <label for="Address">Address:</label>
                <%=Html.TextBox("Address") %>
                <%=Html.ValidationMessage("Address", "*") %>
            </p>
            <p>
                <label for="Country">Country:</label>
                <%=Html.TextBox("Country") %>
                <%=Html.ValidationMessage("Country", "*") %>
            </p>
            <p>
                <label for="ContactPhone">ContactPhone:</label>
                <%=Html.TextBox("ContactPhone") %>
                <%=Html.ValidationMessage("ContactPhone", "*") %>
            </p>
            <p>
                <label for="Latitude">Latitude:</label>
                <%=Html.TextBox("Latitude") %>
                <%=Html.ValidationMessage("Latitude", "*") %>
            </p>
            <p>
                <label for="Longitude">Longitude:</label>
                <%=Html.TextBox("Longitude") %>
                <%=Html.ValidationMessage("Longitude", "*") %>
            </p>
            <p>
                <input type="submit" value="Save"/>
            </p>
        </fieldset>
    <% }
%>
</asp:Content>
```

And now when we run our application and access the *"/Dinners/Create"* URL within the browser it will render UI like below from our Create action implementation:

Implementing the HTTP-POST Create Action Method

We have the HTTP-GET version of our Create action method implemented. When a user clicks the "Save" button it performs a form post to the */Dinners/Create* URL, and submits the HTML <input> form values using the HTTP POST verb.

Let's now implement the HTTP POST behavior of our create action method. We'll begin by adding an overloaded "Create" action method to our DinnersController that has an "AcceptVerbs" attribute on it that indicates it handles HTTP POST scenarios:

```
//
// POST: /Dinners/Create

[AcceptVerbs(HttpVerbs.Post)]
public ActionResult Create() {
    ...
}
```

There are a variety of ways we can access the posted form parameters within our HTTP-POST enabled "Create" method.

One approach is to create a new Dinner object and then use the *UpdateModel()* helper method (like we did with the Edit action) to populate it with the posted form values. We can then add it to our DinnerRepository, persist it to the database, and redirect the user to our Details action to show the newly created Dinner using the code below:

```
//
// POST: /Dinners/Create

[AcceptVerbs(HttpVerbs.Post)]
public ActionResult Create() {

    Dinner dinner = new Dinner();

    try {

        UpdateModel(dinner);

        dinnerRepository.Add(dinner);
        dinnerRepository.Save();

        return RedirectToAction("Details", new {id=dinner.DinnerID});
    }
    catch {

        ModelState.AddRuleViolations(dinner.GetRuleViolations());

        return View(dinner);
    }
}
```

Alternatively, we can use an approach where we have our Create() action method take a Dinner object as a method parameter. ASP.NET MVC will then automatically instantiate a new Dinner object for us, populate its properties using the form inputs, and pass it to our action method:

```
//
//
// POST: /Dinners/Create

[AcceptVerbs(HttpVerbs.Post)]
public ActionResult Create(Dinner dinner) {

    if (ModelState.IsValid) {

        try {
            dinner.HostedBy = "SomeUser";

            dinnerRepository.Add(dinner);
            dinnerRepository.Save();

            return RedirectToAction("Details", new {id = dinner.DinnerID });
        }
        catch {
            ModelState.AddRuleViolations(dinner.GetRuleViolations());
        }
    }

    return View(dinner);
}
```

Our action method above verifies that the Dinner object has been successfully populated with the form post values by checking the ModelState.IsValid property. This will return false if there are input conversion issues (for example: a string of "BOGUS" for the EventDate property), and if there are any issues our action method redisplays the form.

If the input values are valid, then the action method attempts to add and save the new Dinner to the DinnerRepository. It wraps this work within a try/catch block and redisplays the form if there are any business rule violations (which would cause the dinnerRepository.Save() method to raise an exception).

To see this error handling behavior in action, we can request the */Dinners/Create* URL and fill out details about a new Dinner. Incorrect input or values will cause the create form to be redisplayed with the errors highlighted like below:

Notice how our Create form is honoring the exact same validation and business rules as our Edit form. This is because our validation and business rules were defined in the model, and were not embedded within the UI or controller of the application. This means we can later change/evolve our validation or business rules in a single place and have them apply throughout our application. We will not have to change any code within either our Edit or Create action methods to automatically honor any new rules or modifications to existing ones.

When we fix the input values and click the "Save" button again, our addition to the DinnerRepository will succeed, and a new Dinner will be added to the database. We will then be redirected to the */Dinners/Details/[id]* URL – where we will be presented with details about the newly created Dinner:

Delete Support

Let's now add "Delete" support to our DinnersController.

The HTTP-GET Delete Action Method

We'll begin by implementing the HTTP GET behavior of our delete action method. This method will get called when someone visits the */Dinners/Delete/[id]* URL. Below is the implementation:

```
//
// HTTP GET: /Dinners/Delete/1

public ActionResult Delete(int id) {

    Dinner dinner = dinnerRepository.GetDinner(id);

    if (dinner == null)
         return View("NotFound");
    else
        return View(dinner);
}
```

The action method attempts to retrieve the Dinner to be deleted. If the Dinner exists it renders a View based on the Dinner object. If the object doesn't exist (or has already been deleted) it returns a View that renders the "NotFound" view template we created earlier for our "Details" action method.

We can create the "Delete" view template by right-clicking within the Delete action method and selecting the "Add View" context menu command. Within the "Add View" dialog we'll indicate that we are passing a Dinner object to our view template as its model, and choose to create an empty template:

When we click the "Add" button, Visual Studio will add a new "Delete.aspx" view template file for us within our "\Views\Dinners" directory. We'll add some HTML and code to the template to implement a delete confirmation screen like below:

```
<asp:Content ID="Title" ContentPlaceHolderID="TitleContent" runat="server">
    Delete Confirmation:  <%=Html.Encode(Model.Title) %>
</asp:Content>

<asp:Content ID="Main" ContentPlaceHolderID="MainContent" runat="server">

    <h2>
        Delete Confirmation
    </h2>

    <div>
        <p>Please confirm you want to cancel the dinner titled:
           <i> <%=Html.Encode(Model.Title) %>? </i>
        </p>
    </div>

    <% using (Html.BeginForm()) {  %>
        <input name="confirmButton" type="submit" value="Delete" />
    <% } %>

</asp:Content>
```

The code above displays the title of the Dinner to be deleted, and outputs a <form> element that does a POST to the /Dinners/Delete/[id] URL if the end-user clicks the "Delete" button within it.

When we run our application and access the *"/Dinners/Delete/[id]"* URL for a valid Dinner object it renders UI like below:

SIDE TOPIC: WHY ARE WE DOING A POST?

You might ask – why did we go through the effort of creating a <form> within our Delete confirmation screen? Why not just use a standard hyperlink to link to an action method that does the actual delete operation? The reason is because we want to be careful to guard against web-crawlers and search engines discovering our URLs and inadvertently causing data to be deleted when they follow the links. HTTP-GET based URLs are considered "safe" for them to access/crawl, and they are supposed to not follow HTTP-POST ones. A good rule is to make sure you always put destructive or data modifying operations behind HTTP-POST requests.

Implementing the HTTP-POST Delete Action Method

We now have the HTTP-GET version of our Delete action method implemented which displays a delete confirmation screen. When an end user clicks the "Delete" button it will perform a form post to the */Dinners/Dinner/[id]* URL.

Let's now implement the HTTP "POST" behavior of the delete action method using the code below:

```
//
// HTTP POST: /Dinners/Delete/1

[AcceptVerbs(HttpVerbs.Post)]
public ActionResult Delete(int id, string confirmButton) {

    Dinner dinner = dinnerRepository.GetDinner(id);

    if (dinner == null)
        return View("NotFound");

    dinnerRepository.Delete(dinner);
    dinnerRepository.Save();

    return View("Deleted");
}
```

The HTTP-POST version of our Delete action method attempts to retrieve the dinner object to delete. If it can't find it (because it has already been deleted) it renders our "NotFound" template. If it finds the Dinner, it deletes it from the DinnerRepository. It then renders a "Deleted" template.

To implement the "Deleted" template we'll right-click in the action method and choose the "Add View" context menu. We'll name our view "Deleted" and have it be an empty template (and not take a strongly-typed model

object). We'll then add some HTML content to it:

```
<asp:Content ID="Title" ContentPlaceHolderID="TitleContent" runat="server">
    Dinner Deleted
</asp:Content>

<asp:Content ID="Main" ContentPlaceHolderID="MainContent" runat="server">

    <h2>Dinner Deleted</h2>

    <div>
        <p>Your dinner was successfully deleted.</p>
    </div>

    <div>
        <p><a href="/dinners">Click for Upcoming Dinners</a></p>
    </div>

</asp:Content>
```

And now when we run our application and access the *"/Dinners/Delete/[id]"* URL for a valid Dinner object it will render our Dinner delete confirmation screen like below:

When we click the "Delete" button it will perform an HTTP-POST to the */Dinners/Delete/[id]* URL, which will delete the Dinner from our database, and display our "Deleted" view template:

Model Binding Security

We've discussed two different ways to use the built-in model-binding features of ASP.NET MVC. The first using the UpdateModel() method to update properties on an existing model object, and the second using ASP.NET MVC's support for passing model objects in as action method parameters. Both of these techniques are very powerful and extremely useful.

This power also brings with it responsibility. It is important to always be paranoid about security when accepting any user input, and this is also true when binding objects to form input. You should be careful to always HTML encode any user-entered values to avoid HTML and JavaScript injection attacks, and be careful of SQL injection attacks (note: we are using LINQ to SQL for our application, which automatically encodes parameters to prevent these types of attacks). You should never rely on client-side validation alone, and always employ server-side validation to guard against hackers attempting to send you bogus values.

One additional security item to make sure you think about when using the binding features of ASP.NET MVC is the scope of the objects you are binding. Specifically, you want to make sure you understand the security implications of the properties you are allowing to be bound, and make sure you only allow those properties that really should be updatable by an end-user to be updated.

By default, the UpdateModel() method will attempt to update all properties on the model object that match incoming form parameter values. Likewise, objects passed as action method parameters also by default can have all of their properties set via form parameters.

Locking down binding on a per-usage basis

You can lock down the binding policy on a per-usage basis by providing an explicit "include list" of properties that can be updated. This can be done by passing an extra string array parameter to the UpdateModel() method like below:

```
string[] allowedProperties = new[]{ "Title","Description",
                                    "ContactPhone", "Address",
                                    "EventDate", "Latitude",
                                    "Longitude"};

UpdateModel(dinner, allowedProperties);
```

Objects passed as action method parameters also support a [Bind] attribute that enables an "include list" of

allowed properties to be specified like below:

```
//
// POST: /Dinners/Create

[AcceptVerbs(HttpVerbs.Post)]
public ActionResult Create( [Bind(Include="Title,Address")] Dinner dinner ) {
    ...
}
```

Locking down binding on a type basis

You can also lock down the binding rules on a per-type basis. This allows you to specify the binding rules once, and then have them apply in all scenarios (including both UpdateModel and action method parameter scenarios) across all controllers and action methods.

You can customize the per-type binding rules by adding a [Bind] attribute onto a type, or by registering it within the Global.asax file of the application (useful for scenarios where you don't own the type). You can then use the Bind attribute's Include and Exclude properties to control which properties are bindable for the particular class or interface.

We'll use this technique for the Dinner class in our NerdDinner application, and add a [Bind] attribute to it that restricts the list of bindable properties to the following:

```
[Bind(Include="Title,Description,EventDate,Address,Country,ContactPhone,Latitude,Longitude")]
public partial class Dinner {
   ...
}
```

Notice we are not allowing the RSVPs collection to be manipulated via binding, nor are we allowing the DinnerID or HostedBy properties to be set via binding. For security reasons we'll instead only manipulate these particular properties using explicit code within our action methods.

CRUD Wrap-Up

ASP.NET MVC includes a number of built-in features that help with implementing form posting scenarios. We used a variety of these features to provide CRUD UI support on top of our DinnerRepository.

We are using a model-focused approach to implement our application. This means that all our validation and business rule logic is defined within our model layer – and not within our controllers or views. Neither our Controller class nor our View templates know anything about the specific business rules being enforced by our Dinner model class.

This will keep our application architecture clean and make it easier to test. We can add additional business rules to our model layer in the future and *not have to make any code changes* to our Controller or View in order for them to be supported. This is going to provide us with a great deal of agility to evolve and change our application in the future.

Our DinnersController now enables Dinner listings/details, as well as create, edit and delete support. The complete code for the class can be found below:

```
public class DinnersController : Controller {

    DinnerRepository dinnerRepository = new DinnerRepository();

    //
    // GET: /Dinners/

    public ActionResult Index() {
```

```
        var dinners = dinnerRepository.FindUpcomingDinners().ToList();
        return View(dinners);
    }

    //
    // GET: /Dinners/Details/2

    public ActionResult Details(int id) {

        Dinner dinner = dinnerRepository.GetDinner(id);

        if (dinner == null)
            return View("NotFound");
        else
            return View(dinner);
    }

    //
    // GET: /Dinners/Edit/2

    public ActionResult Edit(int id) {

        Dinner dinner = dinnerRepository.GetDinner(id);
        return View(dinner);
    }

    //
    // POST: /Dinners/Edit/2

    [AcceptVerbs(HttpVerbs.Post)]
    public ActionResult Edit(int id, FormCollection formValues) {

        Dinner dinner = dinnerRepository.GetDinner(id);

        try {
            UpdateModel(dinner);

            dinnerRepository.Save();

            return RedirectToAction("Details", new { id= dinner.DinnerID });
        }
        catch {
            ModelState.AddRuleViolations(dinner.GetRuleViolations());

            return View(dinner);
        }
    }

    //
    // GET: /Dinners/Create

    public ActionResult Create() {

        Dinner dinner = new Dinner() {
            EventDate = DateTime.Now.AddDays(7)
        };
        return View(dinner);
    }

    //
    // POST: /Dinners/Create

    [AcceptVerbs(HttpVerbs.Post)]
    public ActionResult Create(Dinner dinner) {

        if (ModelState.IsValid) {

            try {
                dinner.HostedBy = "SomeUser";
```

```
                dinnerRepository.Add(dinner);
                dinnerRepository.Save();

                return RedirectToAction("Details", new{id=dinner.DinnerID});
            }
            catch {
                ModelState.AddRuleViolations(dinner.GetRuleViolations());
            }
        }

        return View(dinner);
    }

    //
    // HTTP GET: /Dinners/Delete/1

    public ActionResult Delete(int id) {

        Dinner dinner = dinnerRepository.GetDinner(id);

        if (dinner == null)
            return View("NotFound");
        else
            return View(dinner);
    }

    //
    // HTTP POST: /Dinners/Delete/1

    [AcceptVerbs(HttpVerbs.Post)]
    public ActionResult Delete(int id, string confirmButton) {

        Dinner dinner = dinnerRepository.GetDinner(id);

        if (dinner == null)
            return View("NotFound");

        dinnerRepository.Delete(dinner);
        dinnerRepository.Save();

        return View("Deleted");
    }
}
```

Next Step

We now have basic CRUD (Create, Read, Update and Delete) support implement within our DinnersController class.

Let's now look at how we can use ViewData and ViewModel classes to enable even richer UI on our forms.

> This is step 6 of a free "NerdDinner" application tutorial that walks-through how to build a small, but complete, web application using ASP.NET MVC 1.
>
> Step 6 shows how enable support for richer form editing scenarios, and also discusses two approaches that can be used to pass data from controllers to views: ViewData and ViewModel.
>
> If you are using ASP.NET MVC 3, we recommend you follow the Getting Started With MVC 3 or MVC Music Store tutorials.

NerdDinner Step 6: ViewData and ViewModel

We've covered a number of form post scenarios, and discussed how to implement create, update and delete (CRUD) support. We'll now take our DinnersController implementation further and enable support for richer form editing scenarios. While doing this we'll discuss two approaches that can be used to pass data from controllers to views: ViewData and ViewModel.

Passing Data from Controllers to View-Templates

One of the defining characteristics of the MVC pattern is the strict "separation of concerns" it helps enforce between the different components of an application. Models, Controllers and Views each have well defined roles and responsibilities, and they communicate amongst each other in well defined ways. This helps promote testability and code reuse.

When a Controller class decides to render an HTML response back to a client, it is responsible for explicitly passing to the view template all of the data needed to render the response. View templates should never perform any data retrieval or application logic – and should instead limit themselves to only have rendering code that is driven off of the model/data passed to it by the controller.

Right now the model data being passed by our DinnersController class to our view templates is simple and straight-forward – a list of Dinner objects in the case of Index(), and a single Dinner object in the case of Details(), Edit(), Create() and Delete(). As we add more UI capabilities to our application, we are often going to need to pass more than just this data to render HTML responses within our view templates. For example, we might want to change the "Country" field within our Edit and Create views from being an HTML textbox to a dropdownlist. Rather than hard-code the dropdown list of country names in the view template, we might want to generate it from a list of supported countries that we populate dynamically. We will need a way to pass both the Dinner object *and* the list of supported countries from our controller to our view templates.

Let's look at two ways we can accomplish this.

Using the ViewData Dictionary

The Controller base class exposes a "ViewData" dictionary property that can be used to pass additional data items from Controllers to Views.

For example, to support the scenario where we want to change the "Country" textbox within our Edit view from being an HTML textbox to a dropdownlist, we can update our Edit() action method to pass (in addition to a Dinner object) a SelectList object that can be used as the model of a countries dropdownlist.

```
//
// GET: /Dinners/Edit/5

[Authorize]
public ActionResult Edit(int id) {

    Dinner dinner = dinnerRepository.GetDinner(id);

    ViewData["Countries"] = new SelectList(PhoneValidator.AllCountries, dinner.Country);

    return View(dinner);
}
```

The constructor of the SelectList above is accepting a list of counties to populate the drop-downlist with, as well as the currently selected value.

We can then update our Edit.aspx view template to use the Html.DropDownList() helper method instead of the Html.TextBox() helper method we used previously:

```
<%= Html.DropDownList("Country", ViewData["Countries"] as SelectList) %>
```

The Html.DropDownList() helper method above takes two parameters. The first is the name of the HTML form element to output. The second is the "SelectList" model we passed via the ViewData dictionary. We are using the C# "as" keyword to cast the type within the dictionary as a SelectList.

And now when we run our application and access the */Dinners/Edit/1* URL within our browser we'll see that our edit UI has been updated to display a dropdownlist of countries instead of a textbox:

Because we also render the Edit view template from the HTTP-POST Edit method (in scenarios when errors occur), we'll want to make sure that we also update this method to add the SelectList to ViewData when the view template is rendered in error scenarios:

```
//
// POST: /Dinners/Edit/5

[AcceptVerbs(HttpVerbs.Post)]
public ActionResult Edit(int id, FormCollection collection) {

    Dinner dinner = dinnerRepository.GetDinner(id);

    try {

        UpdateModel(dinner);

        dinnerRepository.Save();

        return RedirectToAction("Details", new { id=dinner.DinnerID });
    }
    catch {

        ModelState.AddModelErrors(dinner.GetRuleViolations());

        ViewData["countries"] = new SelectList(PhoneValidator.AllCountries, dinner.Country);

        return View(dinner);
    }
}
```

And now our DinnersController edit scenario supports a DropDownList.

Using a ViewModel Pattern

The ViewData dictionary approach has the benefit of being fairly fast and easy to implement. Some developers don't like using string-based dictionaries, though, since typos can lead to errors that will not be caught at compile-time. The un-typed ViewData dictionary also requires using the "as" operator or casting when using a strongly-typed language like C# in a view template.

An alternative approach that we could use is one often referred to as the "ViewModel" pattern. When using this pattern we create strongly-typed classes that are optimized for our specific view scenarios, and which expose properties for the dynamic values/content needed by our view templates. Our controller classes can then populate and pass these view-optimized classes to our view template to use. This enables type-safety, compile-time checking, and editor intellisense within view templates.

For example, to enable dinner form editing scenarios we can create a "DinnerFormViewModel" class like below that exposes two strongly-typed properties: a Dinner object, and the SelectList model needed to populate the countries dropdownlist:

```
public class DinnerFormViewModel {

    // Properties
    public Dinner     Dinner    { get; private set; }
    public SelectList Countries { get; private set; }

    // Constructor
    public DinnerFormViewModel(Dinner dinner) {
        Dinner = dinner;
        Countries = new SelectList(PhoneValidator.AllCountries, dinner.Country);
    }
}
```

We can then update our Edit() action method to create the DinnerFormViewModel using the Dinner object we retrieve from our repository, and then pass it to our view template:

```
//
// GET: /Dinners/Edit/5

[Authorize]
public ActionResult Edit(int id) {

    Dinner dinner = dinnerRepository.GetDinner(id);

    return View(new DinnerFormViewModel(dinner));
}
```

We'll then update our view template so that it expects a "DinnerFormViewModel" instead of a "Dinner" object by changing the "inherits" attribute at the top of the edit.aspx page like so:

```
Inherits="System.Web.Mvc.ViewPage<NerdDinner.Controllers.DinnerFormViewModel>
```

Once we do this, the intellisense of the "Model" property within our view template will be updated to reflect the object model of the DinnerFormViewModel type we are passing it:

We can then update our view code to work off of it. Notice below how we are not changing the names of the input elements we are creating (the form elements will still be named "Title", "Country") – but we are updating the HTML Helper methods to retrieve the values using the DinnerFormViewModel class:

```
<p>
    <label for="Title">Dinner Title:</label>
    <%= Html.TextBox("Title", Model.Dinner.Title) %>
    <%=Html.ValidationMessage("Title", "*") %>
</p>

<p>
    <label for="Country">Country:</label>
    <%= Html.DropDownList("Country", Model.Countries) %>
    <%=Html.ValidationMessage("Country", "*") %>
</p>
```

We'll also update our Edit post method to use the DinnerFormViewModel class when rendering errors:

```
//
// POST: /Dinners/Edit/5

[AcceptVerbs(HttpVerbs.Post)]
public ActionResult Edit(int id, FormCollection collection) {

    Dinner dinner = dinnerRepository.GetDinner(id);

    try {
        UpdateModel(dinner);

        dinnerRepository.Save();

        return RedirectToAction("Details", new { id=dinner.DinnerID });
    }
    catch {
        ModelState.AddModelErrors(dinner.GetRuleViolations());

        return View(new DinnerFormViewModel(dinner));
    }
}
```

We can also update our Create() action methods to re-use the exact same *DinnerFormViewModel* class to enable the countries DropDownList within those as well. Below is the HTTP-GET implementation:

```
//
// GET: /Dinners/Create

public ActionResult Create() {

    Dinner dinner = new Dinner() {
        EventDate = DateTime.Now.AddDays(7)
    };

    return View(new DinnerFormViewModel(dinner));
}
```

Below is the implementation of the HTTP-POST Create method:

```
//
// POST: /Dinners/Create

[AcceptVerbs(HttpVerbs.Post)]
public ActionResult Create(Dinner dinner) {

    if (ModelState.IsValid) {

        try {
            dinner.HostedBy = "SomeUser";

            dinnerRepository.Add(dinner);
            dinnerRepository.Save();

            return RedirectToAction("Details", new { id=dinner.DinnerID });
        }
        catch {
            ModelState.AddModelErrors(dinner.GetRuleViolations());
        }
    }

    return View(new DinnerFormViewModel(dinner));
}
```

And now both our Edit and Create screens support drop-downlists for picking the country.

Custom-shaped ViewModel classes

In the scenario above, our DinnerFormViewModel class directly exposes the Dinner model object as a property, along with a supporting SelectList model property. This approach works fine for scenarios where the HTML UI we want to create within our view template corresponds relatively closely to our domain model objects.

For scenarios where this isn't the case, one option that you can use is to create a custom-shaped ViewModel class whose object model is more optimized for consumption by the view – and which might look completely different from the underlying domain model object. For example, it could potentially expose different property names and/or aggregate properties collected from multiple model objects.

Custom-shaped ViewModel classes can be used both to pass data from controllers to views to render, as well as to help handle form data posted back to a controller's action method. For this later scenario, you might have the action method update a ViewModel object with the form-posted data, and then use the ViewModel instance to map or retrieve an actual domain model object.

Custom-shaped ViewModel classes can provide a great deal of flexibility, and are something to investigate any time you find the rendering code within your view templates or the form-posting code inside your action methods starting to get too complicated. This is often a sign that your domain models don't cleanly correspond to the UI you are generating, and that an intermediate custom-shaped ViewModel class can help.

Next Step

Let's now look at how we can use partials and master-pages to re-use and share UI across our application.

> This is step 7 of a free "NerdDinner" application tutorial that walks-through how to build a small, but complete, web application using ASP.NET MVC 1.
>
> Step 7 looks at ways we can apply the "DRY Principle" within our view templates to eliminate code duplication, using partial view templates and master pages.
>
> If you are using ASP.NET MVC 3, we recommend you follow the Getting Started With MVC 3 or MVC Music Store tutorials.

NerdDinner Step 7: Partials and Master Pages

One of the design philosophies ASP.NET MVC embraces is the "Do Not Repeat Yourself" principle (commonly referred to as "DRY"). A DRY design helps eliminate the duplication of code and logic, which ultimately makes applications faster to build and easier to maintain.

We've already seen the DRY principle applied in several of our NerdDinner scenarios. A few examples: our validation logic is implemented within our model layer, which enables it to be enforced across both edit and create scenarios in our controller; we are re-using the "NotFound" view template across the Edit, Details and Delete action methods; we are using a convention- naming pattern with our view templates, which eliminates the need to explicitly specify the name when we call the View() helper method; and we are re-using the DinnerFormViewModel class for both Edit and Create action scenarios.

Let's now look at ways we can apply the "DRY Principle" within our view templates to eliminate code duplication there as well.

Re-visiting our Edit and Create View Templates

Currently we are using two different view templates – "Edit.aspx" and "Create.aspx" – to display our Dinner form UI. A quick visual comparison of them highlights how similar they are. Below is what the create form looks like:

And here is what our "Edit" form looks like:

Not much of a difference is there? Other than the title and header text, the form layout and input controls are identical.

If we open up the "Edit.aspx" and "Create.aspx" view templates we'll find that they contain identical form layout and input control code. This duplication means we end up having to make changes twice anytime we introduce or change a new Dinner property - which is not good.

Using Partial View Templates

ASP.NET MVC supports the ability to define "partial view" templates that can be used to encapsulate view rendering logic for a sub-portion of a page. "Partials" provide a useful way to define view rendering logic once, and then re-use it in multiple places across an application.

To help "DRY-up" our Edit.aspx and Create.aspx view template duplication, we can create a partial view template named "DinnerForm.ascx" that encapsulates the form layout and input elements common to both. We'll do this by right-clicking on our /Views/Dinners directory and choosing the "Add->View" menu command:

This will display the "Add View" dialog. We'll name the new view we want to create "DinnerForm", select the "Create a partial view" checkbox within the dialog, and indicate that we will pass it a DinnerFormViewModel class:

When we click the "Add" button, Visual Studio will create a new "DinnerForm.ascx" view template for us within the "\Views\Dinners" directory.

We can then copy/paste the duplicate form layout / input control code from our Edit.aspx/ Create.aspx view templates into our new "DinnerForm.ascx" partial view template:

```
<%= Html.ValidationSummary("Please correct the errors and try again.") %>

<% using (Html.BeginForm()) { %>

    <fieldset>
        <p>
            <label for="Title">Dinner Title:</label>
            <%= Html.TextBox("Title", Model.Dinner.Title) %>
            <%=Html.ValidationMessage("Title", "*") %>
        </p>
        <p>
            <label for="EventDate">Event Date:</label>
            <%= Html.TextBox("EventDate", Model.Dinner.EventDate) %>
            <%= Html.ValidationMessage("EventDate", "*") %>
        </p>
        <p>
            <label for="Description">Description:</label>
            <%= Html.TextArea("Description", Model.Dinner.Description) %>
            <%= Html.ValidationMessage("Description", "*") %>
        </p>
        <p>
            <label for="Address">Address:</label>
            <%= Html.TextBox("Address", Model.Dinner.Address) %>
            <%= Html.ValidationMessage("Address", "*") %>
        </p>
        <p>
            <label for="Country">Country:</label>
            <%= Html.DropDownList("Country", Model.Countries) %>
            <%= Html.ValidationMessage("Country", "*") %>
        </p>
        <p>
            <label for="ContactPhone">Contact Phone #:</label>
            <%= Html.TextBox("ContactPhone", Model.Dinner.ContactPhone) %>
            <%= Html.ValidationMessage("ContactPhone", "*") %>
        </p>

        <p>
            <input type="submit" value="Save"/>
        </p>
    </fieldset>

<% } %>
```

We can then update our Edit and Create view templates to call the DinnerForm partial template and eliminate the form duplication. We can do this by calling Html.RenderPartial("DinnerForm") within our view templates:

Create.aspx

```
<asp:Content ID="Title" ContentPlaceHolderID="TitleContent" runat="server">
    Host a Dinner
</asp:Content>

<asp:Content ID="Create" ContentPlaceHolderID="MainContent" runat="server">

    <h2>Host a Dinner</h2>

    <% Html.RenderPartial("DinnerForm"); %>

</asp:Content>
```

Edit.aspx

```
<asp:Content ID="Title" ContentPlaceHolderID="TitleContent" runat="server">
    Edit: <%=Html.Encode(Model.Dinner.Title) %>
</asp:Content>

<asp:Content ID="Edit" ContentPlaceHolderID="MainContent" runat="server">

    <h2>Edit Dinner</h2>

    <% Html.RenderPartial("DinnerForm"); %>

</asp:Content>
```

You can explicitly qualify the path of the partial template you want when calling Html.RenderPartial (for example: ~Views/Dinners/DinnerForm.ascx"). In our code above, though, we are taking advantage of the convention-based naming pattern within ASP.NET MVC, and just specifying "DinnerForm" as the name of the partial to render. When we do this ASP.NET MVC will look first in the convention-based views directory (for DinnersController this would be /Views/Dinners). If it doesn't find the partial template there it will then look for it in the /Views/Shared directory.

When Html.RenderPartial() is called with just the name of the partial view, ASP.NET MVC will pass to the partial view the same Model and ViewData dictionary objects used by the calling view template. Alternatively, there are overloaded versions of Html.RenderPartial() that enable you to pass an alternate Model object and/or ViewData dictionary for the partial view to use. This is useful for scenarios where you only want to pass a subset of the full Model/ViewModel.

SIDE TOPIC: WHY <% %> INSTEAD OF <%= %>?

One of the subtle things you might have noticed with the code above is that we are using a <% %> block instead of a <%= %> block when calling Html.RenderPartial(). <%= %> blocks in ASP.NET indicate that a developer wants to render a specified value (for example: <%= "Hello" %> would render "Hello"). <% %> blocks instead indicate that the developer wants to execute code, and that any rendered output within them must be done explicitly (for example: <% Response.Write("Hello") %>. The reason we are using a <% %> block with our Html.RenderPartial code above is because the Html.RenderPartial() method doesn't return a string, and instead outputs the content directly to the calling view template's output stream. It does this for performance efficiency reasons, and by doing so it avoids the need to create a (potentially very large) temporary string object. This reduces memory usage and improves overall application throughput. One common mistake when using Html.RenderPartial() is to forget to add a semi-colon at the end of the call when it is within a <% %> block. For example, this code will cause a compiler error: <% Html.RenderPartial("DinnerForm") %> You instead need to write: <% Html.RenderPartial("DinnerForm"); %> This is because <% %> blocks are self-contained code statements, and when using C# code statements need to be terminated with a semi-colon.

Using Partial View Templates to Clarify Code

We created the "DinnerForm" partial view template to avoid duplicating view rendering logic in multiple places. This is the most common reason to create partial view templates.

Sometimes it still makes sense to create partial views even when they are only being called in a single place. Very complicated view templates can often become much easier to read when their view rendering logic is extracted and partitioned into one or more well named partial templates.

For example, consider the below code-snippet from the Site.master file in our project (which we will be looking at shortly). The code is relatively straight-forward to read – partly because the logic to display a login/logout link at the top right of the screen is encapsulated within the "LogOnUserControl" partial:

```
<div id="header">
    <div id="title">
        <h1>My MVC Application</h1>
    </div>

    <div id="logindisplay">
        <% Html.RenderPartial("LogOnUserControl"); %>
    </div>

    <div id="menucontainer">

        <ul id="menu">
            <li><%=Html.ActionLink("Home", "Index", "Home")%></li>
            <li><%=Html.ActionLink("About", "About", "Home")%></li>
        </ul>
    </div>
</div>
```

Whenever you find yourself getting confused trying to understand the html/code markup within a view-template, consider whether it wouldn't be clearer if some of it was extracted and refactored into well-named partial views.

Master Pages

In addition to supporting partial views, ASP.NET MVC also supports the ability to create "master page" templates that can be used to define the common layout and top-level html of a site. Content placeholder controls can then be added to the master page to identify replaceable regions that can be overridden or "filled in" by views. This provides a very effective (and DRY) way to apply a common layout across an application.

By default, new ASP.NET MVC projects have a master page template automatically added to them. This master page is named "Site.master" and lives within the \Views\Shared\ folder:

The default Site.master file looks like below. It defines the outer html of the site, along with a menu for navigation at the top. It contains two replaceable content placeholder controls – one for the title, and the other for where the primary content of a page should be replaced:

```
<%@ Master Language="C#" Inherits="System.Web.Mvc.ViewMasterPage"%>
<!DOCTYPE html PUBLIC "-//W3C//DTD XHTML 1.0 Strict//EN" "http://www.w3.org/TR/xhtml1/DTD/xhtml1-strict.dtd">
<html xmlns="http://www.w3.org/1999/xhtml">

<head runat="server">
    <title>
       <asp:ContentPlaceHolder ID="TitleContent" runat="server" />
    </title>
   <link href="../../Content/Site.css" rel="stylesheet" type="text/css" />
</head>

<body>
    <div class="page">

        <div id="header">
            <div id="title">
                <h1>My MVC Application</h1>
            </div>

            <div id="logindisplay">
                <% Html.RenderPartial("LogOnUserControl"); %>
            </div>

            <div id="menucontainer">

                <ul id="menu">
                    <li><%=Html.ActionLink("Home", "Index", "Home")%></li>
                    <li><%=Html.ActionLink("About", "About", "Home")%></li>
                </ul>

            </div>
        </div>

        <div id="main">
            <asp:ContentPlaceHolder ID="MainContent" runat="server" />
        </div>
    </div>
</body>
</html>
```

All of the view templates we've created for our NerdDinner application ("List", "Details", "Edit", "Create", "NotFound", etc) have been based on this Site.master template. This is indicated via the "MasterPageFile" attribute that was added by default to the top <% @ Page %> directive when we created our views using the "Add View" dialog:

```
<%@ Page Inherits="System.Web.Mvc.ViewPage<NerdDinner.Controllers.DinnerViewModel>"
MasterPageFile="~/Views/Shared/Site.Master" %>
```

What this means is that we can change the Site.master content, and have the changes automatically be applied and used when we render any of our view templates.

Let's update our Site.master's header section so that the header of our application is "NerdDinner" instead of "My MVC Application". Let's also update our navigation menu so that the first tab is "Find a Dinner" (handled by the HomeController's Index() action method), and let's add a new tab called "Host a Dinner" (handled by the DinnersController's Create() action method):

```
<div id="header">

    <div id="title">
        <h1>NerdDinner</h1>
    </div>

    <div id="logindisplay">
        <% Html.RenderPartial("LoginStatus"); %>
    </div>

    <div id="menucontainer">
        <ul id="menu">
           <li><%=Html.ActionLink("Find Dinner", "Index", "Home")%></li>
           <li><%=Html.ActionLink("Host Dinner", "Create", "Dinners")%></li>
           <li><%=Html.ActionLink("About", "About", "Home")%></li>
        </ul>
    </div>
</div>
```

When we save the Site.master file and refresh our browser we'll see our header changes show up across all views within our application. For example:

And with the */Dinners/Edit/[id]* URL:

Next Step

Partials and master pages provide very flexible options that enable you to cleanly organize views. You'll find that they help you avoid duplicating view content/ code, and make your view templates easier to read and maintain.

Let's now revisit the listing scenario we built earlier and enable scalable paging support.

> This is step 8 of a free "NerdDinner" application tutorial that walks-through how to build a small, but complete, web application using ASP.NET MVC 1.
>
> Step 8 shows how to add paging support to our /Dinners URL so that instead of displaying 1000s of dinners at once, we'll only display 10 upcoming dinners at a time - and allow end-users to page back and forward through the entire list in an SEO friendly way.
>
> If you are using ASP.NET MVC 3, we recommend you follow the Getting Started With MVC 3 or MVC Music Store tutorials.

NerdDinner Step 8: Paging Support

If our site is successful, it will have thousands of upcoming dinners. We need to make sure that our UI scales to handle all of these dinners, and allows users to browse them. To enable this, we'll add paging support to our */Dinners* URL so that instead of displaying 1000s of dinners at once, we'll only display 10 upcoming dinners at a time - and allow end-users to page back and forward through the entire list in an SEO friendly way.

Index() Action Method Recap

The Index() action method within our DinnersController class currently looks like below:

```
//
// GET: /Dinners/

public ActionResult Index() {

    var dinners = dinnerRepository.FindUpcomingDinners().ToList();
    return View(dinners);
}
```

When a request is made to the */Dinners* URL, it retrieves a list of all upcoming dinners and then renders a listing of all of them out:

Understanding IQueryable<T>

IQueryable<T> is an interface that was introduced with LINQ as part of .NET 3.5. It enables powerful "deferred execution" scenarios that we can take advantage of to implement paging support.

In our DinnerRepository we are returning an IQueryable<Dinner> sequence from our FindUpcomingDinners() method:

```
public class DinnerRepository {

    private NerdDinnerDataContext db = new NerdDinnerDataContext();

    //
    // Query Methods

    public IQueryable<Dinner> FindUpcomingDinners() {

        return from dinner in db.Dinners
               where dinner.EventDate > DateTime.Now
               orderby dinner.EventDate
               select dinner;
    }
```

The IQueryable<Dinner> object returned by our FindUpcomingDinners() method encapsulates a query to retrieve Dinner objects from our database using LINQ to SQL. Importantly, it won't execute the query against the database until we attempt to access/iterate over the data in the query, or until we call the ToList() method on it. The code calling our FindUpcomingDinners() method can optionally choose to add additional "chained" operations/filters to the IQueryable<Dinner> object before executing the query. LINQ to SQL is then smart enough to execute the combined query against the database when the data is requested.

To implement paging logic we can update our DinnersController's Index() action method so that it applies

additional "Skip" and "Take" operators to the returned IQueryable<Dinner> sequence before calling ToList() on it:

```
//
// GET: /Dinners/

public ActionResult Index() {

    var upcomingDinners = dinnerRepository.FindUpcomingDinners();
    var paginatedDinners = upcomingDinners.Skip(10).Take(20).ToList();

    return View(paginatedDinners);
}
```

The above code skips over the first 10 upcoming dinners in the database, and then returns back 20 dinners. LINQ to SQL is smart enough to construct an optimized SQL query that performs this skipping logic in the SQL database – and not in the web-server. This means that even if we have millions of upcoming Dinners in the database, only the 10 we want will be retrieved as part of this request (making it efficient and scalable).

Adding a "page" value to the URL

Instead of hard-coding a specific page range, we'll want our URLs to include a "page" parameter that indicates which Dinner range a user is requesting.

Using a Querystring value

The code below demonstrates how we can update our Index() action method to support a querystring parameter and enable URLs like */Dinners?page=2*:

```
//
// GET: /Dinners/
//      /Dinners?page=2

public ActionResult Index(int? page) {

    const int pageSize = 10;

    var upcomingDinners = dinnerRepository.FindUpcomingDinners();

    var paginatedDinners = upcomingDinners.Skip((page ?? 0) * pageSize)
                                          .Take(pageSize)
                                          .ToList();

    return View(paginatedDinners);
}
```

The Index() action method above has a parameter named "page". The parameter is declared as a nullable integer (that is what int? indicates). This means that the */Dinners?page=2* URL will cause a value of "2" to be passed as the parameter value. The */Dinners* URL (without a querystring value) will cause a null value to be passed.

We are multiplying the page value by the page size (in this case 10 rows) to determine how many dinners to skip over. We are using the C# null "coalescing" operator (??) which is useful when dealing with nullable types. The code above assigns page the value of 0 if the page parameter is null.

Using Embedded URL values

An alternative to using a querystring value would be to embed the page parameter within the actual URL itself. For example: */Dinners/Page/2* or */Dinners/2*. ASP.NET MVC includes a powerful URL routing engine that makes it easy to support scenarios like this.

We can register custom routing rules that map any incoming URL or URL format to any controller class or action method we want. All we need to-do is to open the Global.asax file within our project:

And then register a new mapping rule using the MapRoute() helper method like the first call to routes.MapRoute() below:

```
public void RegisterRoutes(RouteCollection routes) {

   routes.IgnoreRoute("{resource}.axd/{*pathInfo}");

    routes.MapRoute(
        "UpcomingDinners",                              // Route name
        "Dinners/Page/{page}",                          // URL with params
        new { controller = "Dinners", action = "Index" } // Param defaults
    );

    routes.MapRoute(
        "Default",                                      // Route name
        "{controller}/{action}/{id}",                   // URL with params
        new { controller="Home", action="Index",id="" }  // Param defaults
    );
}

void Application_Start() {
    RegisterRoutes(RouteTable.Routes);
}
```

Above we are registering a new routing rule named "UpcomingDinners". We are indicating it has the URL format "Dinners/Page/{page}" – where {page} is a parameter value embedded within the URL. The third parameter to the MapRoute() method indicates that we should map URLs that match this format to the Index() action method on the DinnersController class.

We can use the exact same Index() code we had before with our Querystring scenario – except now our "page" parameter will come from the URL and not the querystring:

```
//
// GET: /Dinners/
//      /Dinners/Page/2

public ActionResult Index(int? page) {

    const int pageSize = 10;

    var upcomingDinners = dinnerRepository.FindUpcomingDinners();

    var paginatedDinners = upcomingDinners.Skip((page ?? 0) * pageSize)
                                          .Take(pageSize)
                                          .ToList();

    return View(paginatedDinners);
}
```

And now when we run the application and type in */Dinners* we'll see the first 10 upcoming dinners:

And when we type in */Dinners/Page/1* we'll see the next page of dinners:

Adding page navigation UI

The last step to complete our paging scenario will be to implement "next" and "previous" navigation UI within our view template to enable users to easily skip over the Dinner data.

To implement this correctly, we'll need to know the total number of Dinners in the database, as well as how many pages of data this translates to. We'll then need to calculate whether the currently requested "page" value is at the beginning or end of the data, and show or hide the "previous" and "next" UI accordingly. We could implement this logic within our Index() action method. Alternatively we can add a helper class to our project that encapsulates this logic in a more re-usable way.

Below is a simple "PaginatedList" helper class that derives from the List<T> collection class built-into the .NET Framework. It implements a re-usable collection class that can be used to paginate any sequence of IQueryable data. In our NerdDinner application we'll have it work over IQueryable<Dinner> results, but it could just as easily be used against IQueryable<Product> or IQueryable<Customer> results in other application scenarios:

```
public class PaginatedList<T> : List<T> {

    public int PageIndex  { get; private set; }
    public int PageSize   { get; private set; }
    public int TotalCount { get; private set; }
    public int TotalPages { get; private set; }

    public PaginatedList(IQueryable<T> source, int pageIndex, int pageSize) {
        PageIndex = pageIndex;
        PageSize = pageSize;
        TotalCount = source.Count();
        TotalPages = (int) Math.Ceiling(TotalCount / (double)PageSize);

        this.AddRange(source.Skip(PageIndex * PageSize).Take(PageSize));
    }

    public bool HasPreviousPage {
        get {
            return (PageIndex > 0);
        }
    }

    public bool HasNextPage {
        get {
            return (PageIndex+1 < TotalPages);
        }
    }
}
```

Notice above how it calculates and then exposes properties like "PageIndex", "PageSize", "TotalCount", and "TotalPages". It also then exposes two helper properties "HasPreviousPage" and "HasNextPage" that indicate whether the page of data in the collection is at the beginning or end of the original sequence. The above code will cause two SQL queries to be run - the first to retrieve the count of the total number of Dinner objects (this doesn't return the objects – rather it performs a "SELECT COUNT" statement that returns an integer), and the second to retrieve just the rows of data we need from our database for the current page of data.

We can then update our DinnersController.Index() helper method to create a PaginatedList<Dinner> from our DinnerRepository.FindUpcomingDinners() result, and pass it to our view template:

```
//
// GET: /Dinners/
//      /Dinners/Page/2

public ActionResult Index(int? page) {

    const int pageSize = 10;

    var upcomingDinners = dinnerRepository.FindUpcomingDinners();
    var paginatedDinners = new PaginatedList<Dinner>(upcomingDinners, page ?? 0, pageSize);

    return View(paginatedDinners);
}
```

We can then update the \Views\Dinners\Index.aspx view template to inherit from ViewPage<NerdDinner.Helpers.PaginatedList<Dinner>> instead of ViewPage<IEnumerable<Dinner>>, and then add the following code to the bottom of our view-template to show or hide next and previous navigation UI:

```
<% if (Model.HasPreviousPage) { %>

    <%= Html.RouteLink("<<<", "UpcomingDinners", new { page = (Model.PageIndex-1) }) %>

<% } %>

<% if (Model.HasNextPage) {  %>

    <%= Html.RouteLink(">>>", "UpcomingDinners", new { page = (Model.PageIndex + 1) }) %>

<% } %>
```

Notice above how we are using the Html.RouteLink() helper method to generate our hyperlinks. This method is similar to the Html.ActionLink() helper method we've used previously. The difference is that we are generating the URL using the "UpcomingDinners" routing rule we setup within our Global.asax file. This ensures that we'll generate URLs to our Index() action method that have the format: */Dinners/Page/{page}* – where the {page} value is a variable we are providing above based on the current PageIndex.

And now when we run our application again we'll see 10 dinners at a time in our browser:

We also have <<< and >>> navigation UI at the bottom of the page that allows us to skip forwards and backwards over our data using search engine accessible URLs:

SIDE TOPIC: UNDERSTANDING THE IMPLICATIONS OF IQUERYABLE<T>

IQueryable<T> is a very powerful feature that enables a variety of interesting deferred execution scenarios (like paging and composition based queries). As with all powerful features, you want to be careful with how you use it and make sure it is not abused. It is important to recognize that returning an IQueryable<T> result from your repository enables calling code to append on chained operator methods to it, and so participate in the ultimate query execution. If you do not want to provide calling code this ability, then you should return back IList<T> or IEnumerable<T> results - which contain the results of a query that has already executed. For pagination scenarios this would require you to push the actual data pagination logic into the repository method being called. In this scenario we might update our FindUpcomingDinners() finder method to have a signature that either returned a PaginatedList: PaginatedList< Dinner> FindUpcomingDinners(int pageIndex, int pageSize) { } Or return back an IList<Dinner>, and use a "totalCount" out param to return the total count of Dinners: IList<Dinner> FindUpcomingDinners(int pageIndex, int pageSize, out int totalCount) { }

Next Step

Let's now look at how we can add authentication and authorization support to our application.

NerdDinner Step 9: Authentication and Authorization

Right now our NerdDinner application grants anyone visiting the site the ability to create and edit the details of any dinner. Let's change this so that users need to register and login to the site to create new dinners, and add a restriction so that only the user who is hosting a dinner can edit it later.

To enable this we'll use authentication and authorization to secure our application.

Understanding Authentication and Authorization

Authentication is the process of identifying and validating the identity of a client accessing an application. Put more simply, it is about identifying "who" the end-user is when they visit a website. ASP.NET supports multiple ways to authenticate browser users. For Internet web applications, the most common authentication approach used is called "Forms Authentication". Forms Authentication enables a developer to author an HTML login form within their application, and then validate the username/password an end-user submits against a database or other password credential store. If the username/password combination is correct, the developer can then ask ASP.NET to issue an encrypted HTTP cookie to identify the user across future requests. We'll by using forms authentication with our NerdDinner application.

Authorization is the process of determining whether an authenticated user has permission to access a particular URL/resource or to perform some action. For example, within our NerdDinner application we'll want to authorize that only users who are logged in can access the */Dinners/Create* URL and create new Dinners. We'll also want to add authorization logic so that only the user who is hosting a dinner can edit it – and deny edit access to all other users.

Forms Authentication and the AccountController

The default Visual Studio project template for ASP.NET MVC automatically enables forms authentication when new ASP.NET MVC applications are created. It also automatically adds a pre-built account login page implementation to the project – which makes it really easy to integrate security within a site.

The default Site.master master page displays a "Log On" link at the top-right of the site when the user accessing it is not authenticated:

Clicking the "Log On" link takes a user to the */Account/LogOn* URL:

Visitors who haven't registered can do so by clicking the "Register" link – which will take them to the */Account/Register* URL and allow them to enter account details:

Clicking the "Register" button will create a new user within the ASP.NET Membership system, and authenticate the user onto the site using forms authentication.

When a user is logged-in, the Site.master changes the top-right of the page to output a "Welcome [username]!" message and renders a "Log Off" link instead of a "Log On" one. Clicking the "Log Off" link logs out the user:

The above login, logout, and registration functionality is implemented within the AccountController class that was added to our project by Visual Studio when it created the project. The UI for the AccountController is implemented using view templates within the \Views\Account directory:

The AccountController class uses the ASP.NET Forms Authentication system to issue encrypted authentication cookies, and the ASP.NET Membership API to store and validate usernames/passwords. The ASP.NET Membership API is extensible and enables any password credential store to be used. ASP.NET ships with built-in membership provider implementations that store username/passwords within a SQL database, or within Active Directory.

We can configure which membership provider our NerdDinner application should use by opening the "web.config" file at the root of the project and looking for the <membership> section within it. The default web.config added when the project was created registers the SQL membership provider, and configures it to use a connection-string named "ApplicationServices" to specify the database location.

The default "ApplicationServices" connection string (which is specified within the <connectionStrings> section of the web.config file) is configured to use SQL Express. It points to a SQL Express database named "ASPNETDB.MDF" under the application's "App_Data" directory. If this database doesn't exist the first time the Membership API is used within the application, ASP.NET will automatically create the database and provision the appropriate membership database schema within it:

If instead of using SQL Express we wanted to use a full SQL Server instance (or connect to a remote database), all we'd need to-do is to update the "ApplicationServices" connection string within the web.config file and make sure that the appropriate membership schema has been added to the database it points at. You can run the

"aspnet_regsql.exe" utility within the \Windows\Microsoft.NET\Framework\v2.0.50727\ directory to add the appropriate schema for membership and the other ASP.NET application services to a database.

Authorizing the /Dinners/Create URL using the [Authorize] filter

We didn't have to write any code to enable a secure authentication and account management implementation for the NerdDinner application. Users can register new accounts with our application, and login/logout of the site.

Now we can add authorization logic to the application, and use the authentication status and username of visitors to control what they can and can't do within the site. Let's begin by adding authorization logic to the "Create" action methods of our DinnersController class. Specifically, we will require that users accessing the */Dinners/Create* URL must be logged in. If they aren't logged in we'll redirect them to the login page so that they can sign-in.

Implementing this logic is pretty easy. All we need to-do is to add an [Authorize] filter attribute to our Create action methods like so:

```
//
// GET: /Dinners/Create

[Authorize]
public ActionResult Create() {
   ...
}

//
// POST: /Dinners/Create

[AcceptVerbs(HttpVerbs.Post), Authorize]
public ActionResult Create(Dinner dinnerToCreate) {
   ...
}
```

ASP.NET MVC supports the ability to create "action filters" that can be used to implement re-usable logic that can be declaratively applied to action methods. The [Authorize] filter is one of the built-in action filters provided by ASP.NET MVC, and it enables a developer to declaratively apply authorization rules to action methods and controller classes.

When applied without any parameters (like above) the [Authorize] filter enforces that the user making the action method request must be logged in – and it will automatically redirect the browser to the login URL if they aren't. When doing this redirect the originally requested URL is passed as a querystring argument (for example: /Account/LogOn?ReturnUrl=%2fDinners%2fCreate). The AccountController will then redirect the user back to the originally requested URL once they login.

The [Authorize] filter optionally supports the ability to specify a "Users" or "Roles" property that can be used to require that the user is both logged in and within a list of allowed users or a member of an allowed security role. For example, the code below only allows two specific users, "scottgu" and "billg", to access the /Dinners/Create URL:

```
[Authorize(Users="scottgu,billg")]
public ActionResult Create() {
    ...
}
```

Embedding specific user names within code tends to be pretty un-maintainable though. A better approach is to define higher-level "roles" that the code checks against, and then to map users into the role using either a database or active directory system (enabling the actual user mapping list to be stored externally from the code). ASP.NET includes a built-in role management API as well as a built-in set of role providers (including ones for SQL

and Active Directory) that can help perform this user/role mapping. We could then update the code to only allow users within a specific "admin" role to access the /Dinners/Create URL:

```
[Authorize(Roles="admin")]
public ActionResult Create() {
   ...
}
```

Using the User.Identity.Name property when Creating Dinners

We can retrieve the username of the currently logged-in user of a request using the User.Identity.Name property exposed on the Controller base class.

Earlier when we implemented the HTTP-POST version of our Create() action method we had hardcoded the "HostedBy" property of the Dinner to a static string. We can now update this code to instead use the User.Identity.Name property, as well as automatically add an RSVP for the host creating the Dinner:

```
//
// POST: /Dinners/Create

[AcceptVerbs(HttpVerbs.Post), Authorize]
public ActionResult Create(Dinner dinner) {

    if (ModelState.IsValid) {

        try {
            dinner.HostedBy = User.Identity.Name;

            RSVP rsvp = new RSVP();
            rsvp.AttendeeName = User.Identity.Name;
            dinner.RSVPs.Add(rsvp);

            dinnerRepository.Add(dinner);
            dinnerRepository.Save();

            return RedirectToAction("Details", new { id=dinner.DinnerID });
        }
        catch {
            ModelState.AddModelErrors(dinner.GetRuleViolations());
        }
    }

    return View(new DinnerFormViewModel(dinner));
}
```

Because we have added an [Authorize] attribute to the Create() method, ASP.NET MVC ensures that the action method only executes if the user visiting the /Dinners/Create URL is logged in on the site. As such, the User.Identity.Name property value will always contain a valid username.

Using the User.Identity.Name property when Editing Dinners

Let's now add some authorization logic that restricts users so that they can only edit the properties of dinners they themselves are hosting.

To help with this, we'll first add an "IsHostedBy(username)" helper method to our Dinner object (within the Dinner.cs partial class we built earlier). This helper method returns true or false depending on whether a supplied username matches the Dinner HostedBy property, and encapsulates the logic necessary to perform a case-insensitive string comparison of them:

```
public partial class Dinner {

    public bool IsHostedBy(string userName) {
        return HostedBy.Equals(userName, StringComparison.InvariantCultureIgnoreCase);
    }
}
```

We'll then add an [Authorize] attribute to the Edit() action methods within our DinnersController class. This will ensure that users must be logged in to request a */Dinners/Edit/[id]* URL.

We can then add code to our Edit methods that uses the Dinner.IsHostedBy(username) helper method to verify that the logged-in user matches the Dinner host. If the user is not the host, we'll display an "InvalidOwner" view and terminate the request. The code to do this looks like below:

```
//
// GET: /Dinners/Edit/5

[Authorize]
public ActionResult Edit(int id) {

    Dinner dinner = dinnerRepository.GetDinner(id);

    if (!dinner.IsHostedBy(User.Identity.Name))
        return View("InvalidOwner");

    return View(new DinnerFormViewModel(dinner));
}

//
// POST: /Dinners/Edit/5

[AcceptVerbs(HttpVerbs.Post), Authorize]
public ActionResult Edit(int id, FormCollection collection) {

    Dinner dinner = dinnerRepository.GetDinner(id);

    if (!dinner.IsHostedBy(User.Identity.Name))
        return View("InvalidOwner");

    try {
        UpdateModel(dinner);

        dinnerRepository.Save();

        return RedirectToAction("Details", new {id = dinner.DinnerID});
    }
    catch {
        ModelState.AddModelErrors(dinnerToEdit.GetRuleViolations());

        return View(new DinnerFormViewModel(dinner));
    }
}
```

We can then right-click on the \Views\Dinners directory and choose the Add->View menu command to create a new "InvalidOwner" view. We'll populate it with the below error message:

```
<asp:Content ID="Title" ContentPlaceHolderID="TitleContent" runat="server">
    You Don't Own This Dinner
</asp:Content>

<asp:Content ID="Main" ContentPlaceHolderID="MainContent" runat="server">

    <h2>Error Accessing Dinner</h2>

    <p>Sorry - but only the host of a Dinner can edit or delete it.</p>

</asp:Content>
```

And now when a user attempts to edit a dinner they don't own, they'll get an error message:

We can repeat the same steps for the Delete() action methods within our controller to lock down permission to delete Dinners as well, and ensure that only the host of a Dinner can delete it.

Showing/Hiding Edit and Delete Links

We are linking to the Edit and Delete action method of our DinnersController class from our Details URL:

Currently we are showing the Edit and Delete action links regardless of whether the visitor to the details URL is the host of the dinner. Let's change this so that the links are only displayed if the visiting user is the owner of the dinner.

The Details() action method within our DinnersController retrieves a Dinner object and then passes it as the model object to our view template:

```
//
// GET: /Dinners/Details/5

public ActionResult Details(int id) {

    Dinner dinner = dinnerRepository.GetDinner(id);

    if (dinner == null)
        return View("NotFound");

    return View(dinner);
}
```

We can update our view template to conditionally show/hide the Edit and Delete links by using the Dinner.IsHostedBy() helper method like below:

```
<% if (Model.IsHostedBy(Context.User.Identity.Name)) { %>

   <%= Html.ActionLink("Edit Dinner", "Edit", new { id=Model.DinnerID }) %> |
   <%= Html.ActionLink("Delete Dinner", "Delete", new {id=Model.DinnerID}) %>

<% } %>
```

Next Steps

Let's now look at how we can enable authenticated users to RSVP for dinners using AJAX.

Use AJAX to Deliver Dynamic Updates

4/10/2020 • 8 minutes to read • Edit Online

by Microsoft

Download PDF

This is step 10 of a free "NerdDinner" application tutorial that walks-through how to build a small, but complete, web application using ASP.NET MVC 1.

Step 10 implements support for logged-in users to RSVP their interest in attending a dinner, using an Ajax-based approach integrated within the dinner details page.

If you are using ASP.NET MVC 3, we recommend you follow the Getting Started With MVC 3 or MVC Music Store tutorials.

NerdDinner Step 10: AJAX Enabling RSVPs Accepts

Let's now implement support for logged-in users to RSVP their interest in attending a dinner. We'll enable this using an AJAX-based approach integrated within the dinner details page.

Indicating whether the user is RSVP'd

Users can visit the */Dinners/Details/[id]* URL to see details about a particular dinner:

The Details() action method is implemented like so:

```
//
// GET: /Dinners/Details/2

public ActionResult Details(int id) {

    Dinner dinner = dinnerRepository.GetDinner(id);

    if (dinner == null)
        return View("NotFound");
    else
        return View(dinner);
}
```

Our first step to implement RSVP support will be to add an "IsUserRegistered(username)" helper method to our Dinner object (within the Dinner.cs partial class we built earlier). This helper method returns true or false depending on whether the user is currently RSVP'd for the Dinner:

```
public partial class Dinner {

    public bool IsUserRegistered(string userName) {
        return RSVPs.Any(r => r.AttendeeName.Equals(userName, StringComparison.InvariantCultureIgnoreCase));
    }
}
```

We can then add the following code to our Details.aspx view template to display an appropriate message indicating whether the user is registered or not for the event:

```
<% if (Request.IsAuthenticated) { %>

    <% if (Model.IsUserRegistered(Context.User.Identity.Name)) { %>

        <p>You are registred for this event!</p>

    <% } else {  %>

        <p>You are not registered for this event</p>

    <% }  %>

<% } else { %>

    <a href="/Account/Logon">Logon</a> to RSVP for this event.

<% } %>
```

And now when a user visits a Dinner they are registered for they'll see this message:

And when they visit a Dinner they are not registered for they'll see the below message:

Implementing the Register Action Method

Let's now add the functionality necessary to enable users to RSVP for a dinner from the details page.

To implement this, we'll create a new "RSVPController" class by right-clicking on the \Controllers directory and

choosing the Add->Controller menu command.

We'll implement a "Register" action method within the new RSVPController class that takes an id for a Dinner as an argument, retrieves the appropriate Dinner object, checks to see if the logged-in user is currently in the list of users who have registered for it, and if not adds an RSVP object for them:

```
public class RSVPController : Controller {

    DinnerRepository dinnerRepository = new DinnerRepository();

    //
    // AJAX: /Dinners/RSVPForEvent/1

    [Authorize, AcceptVerbs(HttpVerbs.Post)]
    public ActionResult Register(int id) {

        Dinner dinner = dinnerRepository.GetDinner(id);

        if (!dinner.IsUserRegistered(User.Identity.Name)) {

            RSVP rsvp = new RSVP();
            rsvp.AttendeeName = User.Identity.Name;

            dinner.RSVPs.Add(rsvp);
            dinnerRepository.Save();
        }

        return Content("Thanks - we'll see you there!");
    }
}
```

Notice above how we are returning a simple string as the output of the action method. We could have embedded this message within a view template – but since it is so small we'll just use the Content() helper method on the controller base class and return a string message like above.

Calling the RSVPForEvent Action Method using AJAX

We'll use AJAX to invoke the Register action method from our Details view. Implementing this is pretty easy. First we'll add two script library references:

```
<script src="/Scripts/MicrosoftAjax.js" type="text/javascript"></script>
<script src="/Scripts/MicrosoftMvcAjax.js" type="text/javascript"></script>
```

The first library references the core ASP.NET AJAX client-side script library. This file is approximately 24k in size (compressed) and contains core client-side AJAX functionality. The second library contains utility functions that integrate with ASP.NET MVC's built-in AJAX helper methods (which we'll use shortly).

We can then update the view template code we added earlier so that instead of outputting a "You are not registered for this event" message, we instead render a link that when pushed performs an AJAX call that invokes our RSVPForEvent action method on our RSVP controller and RSVPs the user:

```
<div id="rsvpmsg">

<% if(Request.IsAuthenticated) { %>

    <% if(Model.IsUserRegistered(Context.User.Identity.Name)) { %>

        <p>You are registred for this event!</p>

    <% } else { %>

        <%= Ajax.ActionLink( "RSVP for this event",
                             "Register", "RSVP",
                             new { id=Model.DinnerID },
                             new AjaxOptions { UpdateTargetId="rsvpmsg"}) %>
    <% } %>

<% } else { %>

    <a href="/Account/Logon">Logon</a> to RSVP for this event.

<% } %>

</div>
```

The Ajax.ActionLink() helper method used above is built-into ASP.NET MVC and is similar to the Html.ActionLink() helper method except that instead of performing a standard navigation it makes an AJAX call to the action method when the link is clicked. Above we are calling the "Register" action method on the "RSVP" controller and passing the DinnerID as the "id" parameter to it. The final AjaxOptions parameter we are passing indicates that we want to take the content returned from the action method and update the HTML element on the page whose id is "rsvpmsg".

And now when a user browses to a dinner they aren't registered for yet they'll see a link to RSVP for it:

If they click the "RSVP for this event" link they'll make an AJAX call to the Register action method on the RSVP

controller, and when it completes they'll see an updated message like below:

The network bandwidth and traffic involved when making this AJAX call is really lightweight. When the user clicks on the "RSVP for this event" link, a small HTTP POST network request is made to the */Dinners/Register/1* URL that looks like below on the wire:

```
POST /Dinners/Register/49 HTTP/1.1
X-Requested-With: XMLHttpRequest
Content-Type: application/x-www-form-urlencoded; charset=utf-8
Referer: http://localhost:8080/Dinners/Details/49
```

And the response from our Register action method is simply:

```
HTTP/1.1 200 OK
Content-Type: text/html; charset=utf-8
Content-Length: 29
Thanks - we'll see you there!
```

This lightweight call is fast and will work even over a slow network.

Adding a jQuery Animation

The AJAX functionality we implemented works well and fast. Sometimes it can happen so fast, though, that a user might not notice that the RSVP link has been replaced with new text. To make the outcome a little more obvious we can add a simple animation to draw attention to the update message.

The default ASP.NET MVC project template includes jQuery – an excellent (and very popular) open source JavaScript library that is also supported by Microsoft. jQuery provides a number of features, including a nice HTML DOM selection and effects library.

To use jQuery we'll first add a script reference to it. Because we are going to be using jQuery within a variety of places within our site, we'll add the script reference within our Site.master master page file so that all pages can

use it.

```
<script src="/Scripts/jQuery-1.3.2.js" type="text/javascript"></script>
```

Tip: make sure you have installed the JavaScript intellisense hotfix for VS 2008 SP1 that enables richer intellisense support for JavaScript files (including jQuery). You can download it from: http://tinyurl.com/vs2008javascripthotfix

Code written using JQuery often uses a global "$()" JavaScript method that retrieves one or more HTML elements using a CSS selector. For example, *$("#rsvpmsg")* selects any HTML element with the id of rsvpmsg, while *$(".something")* would select all elements with the "something" CSS class name. You can also write more advanced queries like "return all of the checked radio buttons" using a selector query like: *$("input[@type=radio][@checked]")*.

Once you've selected elements, you can call methods on them to take action, like hiding them: *$("#rsvpmsg").hide();*

For our RSVP scenario, we'll define a simple JavaScript function named "AnimateRSVPMessage" that selects the "rsvpmsg" and animates the size of its text content. The below code starts the text small and then causes it to increase over a 400 milliseconds timeframe:

```
<script type="text/javascript">

    function AnimateRSVPMessage() {
        $("#rsvpmsg").animate({fontSize: "1.5em"},400);
    }

</script>
```

We can then wire-up this JavaScript function to be called after our AJAX call successfully completes by passing its name to our Ajax.ActionLink() helper method (via the AjaxOptions "OnSuccess" event property):

```
<%= Ajax.ActionLink( "RSVP for this event",
                     "Register", "RSVP",
                     new { id=Model.DinnerID },
                     new AjaxOptions { UpdateTargetId="rsvpmsg",
                                       OnSuccess="AnimateRSVPMessage"}) %>
```

And now when the "RSVP for this event" link is clicked and our AJAX call completes successfully, the content message sent back will animate and grow large:

In addition to providing an "OnSuccess" event, the AjaxOptions object exposes OnBegin, OnFailure, and OnComplete events that you can handle (along with a variety of other properties and useful options).

Cleanup - Refactor out a RSVP Partial View

Our details view template is starting to get a little long, which overtime will make it a little harder to understand. To help improve the code readability, let's finish up by creating a partial view – RSVPStatus.ascx – that encapsulate all of the RSVP view code for our Details page.

We can do this by right-clicking on the \Views\Dinners folder and then choosing the Add->View menu command. We'll have it take a Dinner object as its strongly-typed ViewModel. We can then copy/paste the RSVP content from our Details.aspx view into it.

Once we've done that, let's also create another partial view – EditAndDeleteLinks.ascx - that encapsulates our Edit and Delete link view code. We'll also have it take a Dinner object as its strongly-typed ViewModel, and copy/paste the Edit and Delete logic from our Details.aspx view into it.

Our details view template can then just include two Html.RenderPartial() method calls at the bottom:

```
<asp:Content ID="Title" ContentPlaceHolderID="TitleContent"runat="server">
    <%= Html.Encode(Model.Title) %>
</asp:Content>

<asp:Content ID="details" ContentPlaceHolderID="MainContent" runat="server">

    <div id="dinnerDiv">

        <h2><%=Html.Encode(Model.Title) %></h2>
        <p>
            <strong>When:</strong>
            <%=Model.EventDate.ToShortDateString() %>

            <strong>@</strong>
            <%=Model.EventDate.ToShortTimeString() %>
        </p>
        <p>
            <strong>Where:</strong>
            <%=Html.Encode(Model.Address) %>,
            <%=Html.Encode(Model.Country) %>
        </p>
         <p>
            <strong>Description:</strong>
            <%=Html.Encode(Model.Description) %>
        </p>
        <p>
            <strong>Organizer:</strong>
            <%=Html.Encode(Model.HostedBy) %>
            (<%=Html.Encode(Model.ContactPhone) %>)
        </p>

        <% Html.RenderPartial("RSVPStatus"); %>
        <% Html.RenderPartial("EditAndDeleteLinks"); %>

    </div>

</asp:Content>
```

This makes the code cleaner to read and maintain.

Next Step

Let's now look at how we can use AJAX even further and add interactive mapping support to our application.

> This is step 11 of a free "NerdDinner" application tutorial that walks-through how to build a small, but complete, web application using ASP.NET MVC 1.
>
> Step 11 shows how to integrate AJAX mapping support into our NerdDinner application, enabling users who are creating, editing or viewing dinners to see the location of the dinner graphically.
>
> If you are using ASP.NET MVC 3, we recommend you follow the Getting Started With MVC 3 or MVC Music Store tutorials.

NerdDinner Step 11: Integrating an AJAX Map

We'll now make our application a little more visually exciting by integrating AJAX mapping support. This will enable users who are creating, editing or viewing dinners to see the location of the dinner graphically.

Creating a Map Partial View

We are going to use mapping functionality in several places within our application. To keep our code DRY we'll encapsulate the common map functionality within a single partial template that we can re-use across multiple controller actions and views. We'll name this partial view "map.ascx" and create it within the \Views\Dinners directory.

We can create the map.ascx partial by right-clicking on the \Views\Dinners directory and choosing the Add->View menu command. We'll name the view "Map.ascx", check it as a partial view, and indicate that we are going to pass it a strongly-typed "Dinner" model class:

When we click the "Add" button our partial template will be created. We'll then update the Map.ascx file to have the following content:

```
<script src="http://dev.virtualearth.net/mapcontrol/mapcontrol.ashx?v=6.2" type="text/javascript"></script>
<script src="/Scripts/Map.js" type="text/javascript"></script>

<div id="theMap">
</div>

<script type="text/javascript">

    $(document).ready(function() {
        var latitude = <%=Model.Latitude%>;
        var longitude = <%=Model.Longitude%>;

        if ((latitude == 0) || (longitude == 0))
            LoadMap();
        else
            LoadMap(latitude, longitude, mapLoaded);
    });

   function mapLoaded() {
        var title = "<%=Html.Encode(Model.Title) %>";
        var address = "<%=Html.Encode(Model.Address) %>";

        LoadPin(center, title, address);
        map.SetZoomLevel(14);
    }

</script>
```

The first <script> reference points to the Microsoft Virtual Earth 6.2 mapping library. The second <script> reference points to a map.js file that we will shortly create which will encapsulate our common Javascript mapping logic. The element is the HTML container that Virtual Earth will use to host the map.

We then have an embedded <script> block that contains two JavaScript functions specific to this view. The first function uses jQuery to wire-up a function that executes when the page is ready to run client-side script. It calls a LoadMap() helper function that we'll define within our Map.js script file to load the virtual earth map control. The second function is a callback event handler that adds a pin to the map that identifies a location.

Notice how we are using a server-side <%= %> block within the client-side script block to embed the latitude and longitude of the Dinner we want to map into the JavaScript. This is a useful technique to output dynamic values that can be used by client-side script (without requiring a separate AJAX call back to the server to retrieve the values – which makes it faster). The <%= %> blocks will execute when the view is rendering on the server – and so the output of the HTML will just end up with embedded JavaScript values (for example: var latitude = 47.64312;).

Creating a Map.js utility library

Let's now create the Map.js file that we can use to encapsulate the JavaScript functionality for our map (and implement the LoadMap and LoadPin methods above). We can do this by right-clicking on the \Scripts directory within our project, and then choose the "Add->New Item" menu command, select the JScript item, and name it "Map.js".

Below is the JavaScript code we'll add to the Map.js file that will interact with Virtual Earth to display our map and add locations pins to it for our dinners:

```
var map = null;
var points = [];
var shapes = [];
var center = null;

function LoadMap(latitude, longitude, onMapLoaded) {
    map = new VEMap('theMap');
```

```
    options = new VEMapOptions();
    options.EnableBirdseye = false;

    // Makes the control bar less obtrusize.
    map.SetDashboardSize(VEDashboardSize.Small);

    if (onMapLoaded != null)
        map.onLoadMap = onMapLoaded;

    if (latitude != null && longitude != null) {
        center = new VELatLong(latitude, longitude);
    }

    map.LoadMap(center, null, null, null, null, null, null, options);
}

function LoadPin(LL, name, description) {
    var shape = new VEShape(VEShapeType.Pushpin, LL);

    //Make a nice Pushpin shape with a title and description
    shape.SetTitle("<span class=\"pinTitle\"> " + escape(name) + "</span>");
    if (description !== undefined) {
        shape.SetDescription("<p class=\"pinDetails\">" +
        escape(description) + "</p>");
    }
    map.AddShape(shape);
    points.push(LL);
    shapes.push(shape);
}

function FindAddressOnMap(where) {
    var numberOfResults = 20;
    var setBestMapView = true;
    var showResults = true;

    map.Find("", where, null, null, null,
           numberOfResults, showResults, true, true,
           setBestMapView, callbackForLocation);
}

function callbackForLocation(layer, resultsArray, places,
            hasMore, VEErrorMessage) {

    clearMap();

    if (places == null)
        return;

    //Make a pushpin for each place we find
    $.each(places, function(i, item) {
        description = "";
        if (item.Description !== undefined) {
            description = item.Description;
        }
        var LL = new VELatLong(item.LatLong.Latitude,
                        item.LatLong.Longitude);

        LoadPin(LL, item.Name, description);
    });

    //Make sure all pushpins are visible
    if (points.length > 1) {
        map.SetMapView(points);
    }

    //If we've found exactly one place, that's our address.
    if (points.length === 1) {
        $("#Latitude").val(points[0].Latitude);
        $("#Longitude").val(points[0].Longitude);
```

```
    }
}

function clearMap() {
    map.Clear();
    points = [];
    shapes = [];
}
```

Integrating the Map with Create and Edit Forms

We'll now integrate the Map support with our existing Create and Edit scenarios. The good news is that this is pretty easy to-do, and doesn't require us to change any of our Controller code. Because our Create and Edit views share a common "DinnerForm" partial view to implement the dinner form UI, we can add the map in one place and have both our Create and Edit scenarios use it.

All we need to-do is to open the \Views\Dinners\DinnerForm.ascx partial view and update it to include our new map partial. Below is what the updated DinnerForm will look like once the map is added (note: the HTML form elements are omitted from the code snippet below for brevity):

```
<%= Html.ValidationSummary() %>

<% using (Html.BeginForm()) { %>

    <fieldset>

        <div id="dinnerDiv">
            <p>
               [HTML Form Elements Removed for Brevity]
            </p>
            <p>
               <input type="submit" value="Save"/>
            </p>
        </div>

        <div id="mapDiv">
            <%Html.RenderPartial("Map", Model.Dinner); %>
        </div>

    </fieldset>

    <script type="text/javascript">

        $(document).ready(function() {
            $("#Address").blur(function(evt) {
                $("#Latitude").val("");
                $("#Longitude").val("");

                var address = jQuery.trim($("#Address").val());
                if (address.length < 1)
                    return;

                FindAddressOnMap(address);
            });
        });

    </script>

<% } %>
```

The DinnerForm partial above takes an object of type "DinnerFormViewModel" as its model type (because it needs both a Dinner object, as well as a SelectList to populate the dropdownlist of countries). Our Map partial just needs an object of type "Dinner" as its model type, and so when we render the map partial we are passing just the

Dinner sub-property of DinnerFormViewModel to it:

```
<% Html.RenderPartial("Map", Model.Dinner); %>
```

The JavaScript function we've added to the partial uses jQuery to attach a "blur" event to the "Address" HTML textbox. You've probably heard of "focus" events that fire when a user clicks or tabs into a textbox. The opposite is a "blur" event that fires when a user exits a textbox. The above event handler clears the latitude and longitude textbox values when this happens, and then plots the new address location on our map. A callback event handler that we defined within the map.js file will then update the longitude and latitude textboxes on our form using values returned by virtual earth based on the address we gave it.

And now when we run our application again and click the "Host Dinner" tab we'll see a default map displayed along with our standard Dinner form elements:

When we type in an address, and then tab away, the map will dynamically update to display the location, and our event handler will populate the latitude/longitude textboxes with the location values:

If we save the new dinner and then open it again for editing, we'll find that the map location is displayed when the page loads:

Every time the address field is changed, the map and the latitude/longitude coordinates will update.

Now that the map displays the Dinner location, we can also change the Latitude and Longitude form fields from being visible textboxes to instead be hidden elements (since the map is automatically updating them each time an address is entered). To-do this we'll switch from using the Html.TextBox() HTML helper to using the Html.Hidden() helper method:

```
<p>
    <%= Html.Hidden("Latitude", Model.Dinner.Latitude)%>
    <%= Html.Hidden("Longitude", Model.Dinner.Longitude)%>
</p>
```

And now our forms are a little more user-friendly and avoid displaying the raw latitude/longitude (while still storing them with each Dinner in the database):

Integrating the Map with the Details View

Now that we have the map integrated with our Create and Edit scenarios, let's also integrate it with our Details scenario. All we need to-do is to call <% Html.RenderPartial("map"); %> within the Details view.

Below is what the source code to the complete Details view (with map integration) looks like:

```
<asp:Content ID="Title" ContentPlaceHolderID="TitleContent"runat="server">
    <%= Html.Encode(Model.Title) %>
</asp:Content>

<asp:Content ID="details" ContentPlaceHolderID="MainContent" runat="server">

    <div id="dinnerDiv">

        <h2><%=Html.Encode(Model.Title) %></h2>
        <p>
            <strong>When:</strong>
            <%=Model.EventDate.ToShortDateString() %>

            <strong>@</strong>
            <%=Model.EventDate.ToShortTimeString() %>
        </p>
        <p>
            <strong>Where:</strong>
            <%=Html.Encode(Model.Address) %>,
            <%=Html.Encode(Model.Country) %>
        </p>
         <p>
            <strong>Description:</strong>
            <%=Html.Encode(Model.Description) %>
        </p>
        <p>
            <strong>Organizer:</strong>
            <%=Html.Encode(Model.HostedBy) %>
            (<%=Html.Encode(Model.ContactPhone) %>)
        </p>

        <%Html.RenderPartial("RSVPStatus"); %>
        <%Html.RenderPartial("EditAndDeleteLinks"); %>

    </div>

    <div id="mapDiv">
        <%Html.RenderPartial("map"); %>
    </div>

</asp:Content>
```

And now when a user navigates to a /Dinners/Details/[id] URL they'll see details about the dinner, the location of the dinner on the map (complete with a push-pin that when hovered over displays the title of the dinner and the address of it), and have an AJAX link to RSVP for it:

Implementing Location Search in our Database and Repository

To finish off our AJAX implementation, let's add a Map to the home page of the application that allows users to graphically search for dinners near them.

We'll begin by implementing support within our database and data repository layer to efficiently perform a location-based radius search for Dinners. We could use the new geospatial features of SQL 2008 to implement this, or alternatively we can use a SQL function approach that Gary Dryden discussed in article here: http://www.codeproject.com/KB/cs/distancebetweenlocations.aspx and Rob Conery blogged about using with LINQ to SQL here: http://blog.wekeroad.com/2007/08/30/linq-and-geocoding/

To implement this technique, we will open the "Server Explorer" within Visual Studio, select the NerdDinner database, and then right-click on the "functions" sub-node under it and choose to create a new "Scalar-valued function":

We'll then paste in the following DistanceBetween function:

```
CREATE FUNCTION [dbo].[DistanceBetween](@Lat1 as real,
                @Long1 as real, @Lat2 as real, @Long2 as real)
RETURNS real
AS
BEGIN

DECLARE @dLat1InRad as float(53);
SET @dLat1InRad = @Lat1 * (PI()/180.0);
DECLARE @dLong1InRad as float(53);
SET @dLong1InRad = @Long1 * (PI()/180.0);
DECLARE @dLat2InRad as float(53);
SET @dLat2InRad = @Lat2 * (PI()/180.0);
DECLARE @dLong2InRad as float(53);
SET @dLong2InRad = @Long2 * (PI()/180.0);

DECLARE @dLongitude as float(53);
SET @dLongitude = @dLong2InRad - @dLong1InRad;
DECLARE @dLatitude as float(53);
SET @dLatitude = @dLat2InRad - @dLat1InRad;
/* Intermediate result a. */
DECLARE @a as float(53);
SET @a = SQUARE (SIN (@dLatitude / 2.0)) + COS (@dLat1InRad)
                 * COS (@dLat2InRad)
                 * SQUARE(SIN (@dLongitude / 2.0));
/* Intermediate result c (great circle distance in Radians). */
DECLARE @c as real;
SET @c = 2.0 * ATN2 (SQRT (@a), SQRT (1.0 - @a));
DECLARE @kEarthRadius as real;
/* SET kEarthRadius = 3956.0 miles */
SET @kEarthRadius = 6376.5;        /* kms */

DECLARE @dDistance as real;
SET @dDistance = @kEarthRadius * @c;
return (@dDistance);
END
```

We'll then create a new table-valued function in SQL Server that we'll call "NearestDinners":

This "NearestDinners" table function uses the DistanceBetween helper function to return all Dinners within 100 miles of the latitude and longitude we supply it:

```
CREATE FUNCTION [dbo].[NearestDinners]
      (
      @lat real,
      @long real
      )
RETURNS  TABLE
AS
      RETURN
      SELECT Dinners.DinnerID
      FROM   Dinners
      WHERE  dbo.DistanceBetween(@lat, @long, Latitude, Longitude) <100
```

To call this function, we'll first open up the LINQ to SQL designer by double-clicking on the NerdDinner.dbml file within our \Models directory:

We'll then drag the NearestDinners and DistanceBetween functions onto the LINQ to SQL designer, which will cause them to be added as methods on our LINQ to SQL NerdDinnerDataContext class:

We can then expose a "FindByLocation" query method on our DinnerRepository class that uses the NearestDinner function to return upcoming Dinners that are within 100 miles of the specified location:

```
public IQueryable<Dinner> FindByLocation(float latitude, float longitude) {

   var dinners = from dinner in FindUpcomingDinners()
                 join i in db.NearestDinners(latitude, longitude)
                 on dinner.DinnerID equals i.DinnerID
                 select dinner;

   return dinners;
}
```

Implementing a JSON-based AJAX Search Action Method

We'll now implement a controller action method that takes advantage of the new FindByLocation() repository method to return back a list of Dinner data that can be used to populate a map. We'll have this action method return back the Dinner data in a JSON (JavaScript Object Notation) format so that it can be easily manipulated using JavaScript on the client.

To implement this, we'll create a new "SearchController" class by right-clicking on the \Controllers directory and choosing the Add->Controller menu command. We'll then implement a "SearchByLocation" action method within the new SearchController class like below:

```
public class JsonDinner {
    public int      DinnerID    { get; set; }
    public string   Title       { get; set; }
    public double   Latitude    { get; set; }
    public double   Longitude   { get; set; }
    public string   Description { get; set; }
    public int      RSVPCount   { get; set; }
}

public class SearchController : Controller {

    DinnerRepository dinnerRepository = new DinnerRepository();

    //
    // AJAX: /Search/SearchByLocation

    [AcceptVerbs(HttpVerbs.Post)]
    public ActionResult SearchByLocation(float longitude, float latitude) {

        var dinners = dinnerRepository.FindByLocation(latitude,longitude);

        var jsonDinners = from dinner in dinners
                          select new JsonDinner {
                              DinnerID = dinner.DinnerID,
                              Latitude = dinner.Latitude,
                              Longitude = dinner.Longitude,
                              Title = dinner.Title,
                              Description = dinner.Description,
                              RSVPCount = dinner.RSVPs.Count
                          };

        return Json(jsonDinners.ToList());
    }
}
```

The SearchController's SearchByLocation action method internally calls the FindByLocation method on DinnerRepository to get a list of nearby dinners. Rather than return the Dinner objects directly to the client, though, it instead returns JsonDinner objects. The JsonDinner class exposes a subset of Dinner properties (for example: for security reasons it doesn't disclose the names of the people who have RSVP'd for a dinner). It also includes an RSVPCount property that doesn't exist on Dinner– and which is dynamically calculated by counting the number of RSVP objects associated with a particular dinner.

We are then using the Json() helper method on the Controller base class to return the sequence of dinners using a JSON-based wire format. JSON is a standard text format for representing simple data-structures. Below is an example of what a JSON-formatted list of two JsonDinner objects looks like when returned from our action method:

```
[{"DinnerID":53,"Title":"Dinner with the Family","Latitude":47.64312,"Longitude":-
122.130609,"Description":"Fun dinner","RSVPCount":2},
{"DinnerID":54,"Title":"Another Dinner","Latitude":47.632546,"Longitude":-122.21201,"Description":"Dinner with
Friends","RSVPCount":3}]
```

Calling the JSON-based AJAX method using jQuery

We are now ready to update the home page of the NerdDinner application to use the SearchController's SearchByLocation action method. To-do this, we'll open the /Views/Home/Index.aspx view template and update it to have a textbox, search button, our map, and a element named dinnerList:

```
<h2>Find a Dinner</h2>

<div id="mapDivLeft">

    <div id="searchBox">
        Enter your location: <%=Html.TextBox("Location") %>
        <input id="search" type="submit" value="Search"/>
    </div>

    <div id="theMap">
    </div>

</div>

<div id="mapDivRight">
    <div id="dinnerList"></div>
</div>
```

We can then add two JavaScript functions to the page:

```
<script type="text/javascript">

    $(document).ready(function() {
        LoadMap();
    });

    $("#search").click(function(evt) {
        var where = jQuery.trim($("#Location").val());
        if (where.length < 1)
            return;

        FindDinnersGivenLocation(where);
    });

</script>
```

The first JavaScript function loads the map when the page first loads. The second JavaScript function wires up a JavaScript click event handler on the search button. When the button is pressed it calls the FindDinnersGivenLocation() JavaScript function which we'll add to our Map.js file:

```
function FindDinnersGivenLocation(where) {
    map.Find("", where, null, null, null, null, null, false,
       null, null, callbackUpdateMapDinners);
}
```

This FindDinnersGivenLocation() function calls map.Find() on the Virtual Earth Control to center it on the entered location. When the virtual earth map service returns, the map.Find() method invokes the callbackUpdateMapDinners callback method we passed it as the final argument.

The callbackUpdateMapDinners() method is where the real work is done. It uses jQuery's $.post() helper method to perform an AJAX call to our SearchController's SearchByLocation() action method – passing it the latitude and longitude of the newly centered map. It defines an inline function that will be called when the $.post() helper method completes, and the JSON-formatted dinner results returned from the SearchByLocation() action method will be passed it using a variable called "dinners". It then does a foreach over each returned dinner, and uses the dinner's latitude and longitude and other properties to add a new pin on the map. It also adds a dinner entry to the HTML list of dinners to the right of the map. It then wires-up a hover event for both the pushpins and the HTML list so that details about the dinner are displayed when a user hovers over them:

```
function callbackUpdateMapDinners(layer, resultsArray, places, hasMore, VEErrorMessage) {

    $("#dinnerList").empty();
    clearMap();
    var center = map.GetCenter();

    $.post("/Search/SearchByLocation", { latitude: center.Latitude,
                                         longitude: center.Longitude },
    function(dinners) {
        $.each(dinners, function(i, dinner) {

            var LL = new VELatLong(dinner.Latitude,
                                   dinner.Longitude, 0, null);

            var RsvpMessage = "";

            if (dinner.RSVPCount == 1)
                RsvpMessage = "" + dinner.RSVPCount + "RSVP";
            else
                RsvpMessage = "" + dinner.RSVPCount + "RSVPs";

            // Add Pin to Map
            LoadPin(LL, '<a href="/Dinners/Details/' + dinner.DinnerID + '">'
                        + dinner.Title + '</a>',
                        "<p>" + dinner.Description + "</p>" + RsvpMessage);

            //Add a dinner to the <ul> dinnerList on the right
            $('#dinnerList').append($('<li/>')
                            .attr("class", "dinnerItem")
                            .append($('<a/>').attr("href",
                                      "/Dinners/Details/" + dinner.DinnerID)
                            .html(dinner.Title))
                            .append(" ("+RsvpMessage+")"));
        });

        // Adjust zoom to display all the pins we just added.
        map.SetMapView(points);

        // Display the event's pin-bubble on hover.
        $(".dinnerItem").each(function(i, dinner) {
            $(dinner).hover(
                function() { map.ShowInfoBox(shapes[i]); },
                function() { map.HideInfoBox(shapes[i]); }
            );
        });
    }, "json");
```

And now when we run the application and visit the home-page we'll be presented with a map. When we enter the name of a city the map will display the upcoming dinners near it:

Hovering over a dinner will display details about it.

Clicking the Dinner title either in the bubble or on the right-hand side in the HTML list will navigate us to the dinner – which we can then optionally RSVP for:

Next Step

We've now implemented all the application functionality of our NerdDinner application. Let's now look at how we can enable automated unit testing of it.

> This is step 12 of a free "NerdDinner" application tutorial that walks-through how to build a small, but complete, web application using ASP.NET MVC 1.
>
> Step 12 shows how to develop a suite of automated unit tests that verify our NerdDinner functionality, and which will give us the confidence to make changes and improvements to the application in the future.
>
> If you are using ASP.NET MVC 3, we recommend you follow the Getting Started With MVC 3 or MVC Music Store tutorials.

NerdDinner Step 12: Unit Testing

Let's develop a suite of automated unit tests that verify our NerdDinner functionality, and which will give us the confidence to make changes and improvements to the application in the future.

Why Unit Test?

On the drive into work one morning you have a sudden flash of inspiration about an application you are working on. You realize there is a change you can implement that will make the application dramatically better. It might be a refactoring that cleans up the code, adds a new feature, or fixes a bug.

The question that confronts you when you arrive at your computer is – "how safe is it to make this improvement?" What if making the change has side effects or breaks something? The change might be simple and only take a few minutes to implement, but what if it takes hours to manually test out all of the application scenarios? What if you forget to cover a scenario and a broken application goes into production? Is making this improvement really worth all the effort?

Automated unit tests can provide a safety net that enables you to continually enhance your applications, and avoid being afraid of the code you are working on. Having automated tests that quickly verify functionality enables you to code with confidence – and empower you to make improvements you might otherwise not have felt comfortable doing. They also help create solutions that are more maintainable and have a longer lifetime - which leads to a much higher return on investment.

The ASP.NET MVC Framework makes it easy and natural to unit test application functionality. It also enables a Test Driven Development (TDD) workflow that enables test-first based development.

NerdDinner.Tests Project

When we created our NerdDinner application at the beginning of this tutorial, we were prompted with a dialog asking whether we wanted to create a unit test project to go along with the application project:

We kept the "Yes, create a unit test project" radio button selected – which resulted in a "NerdDinner.Tests" project being added to our solution:

The NerdDinner.Tests project references the NerdDinner application project assembly, and enables us to easily add automated tests to it that verify the application functionality.

Creating Unit Tests for our Dinner Model Class

Let's add some tests to our NerdDinner.Tests project that verify the Dinner class we created when we built our model layer.

We'll start by creating a new folder within our test project called "Models" where we'll place our model-related tests. We'll then right-click on the folder and choose the **Add->New Test** menu command. This will bring up the "Add New Test" dialog.

We'll choose to create a "Unit Test" and name it "DinnerTest.cs":

When we click the "ok" button Visual Studio will add (and open) a DinnerTest.cs file to the project:

The default Visual Studio unit test template has a bunch of boiler-plate code within it that I find a little messy. Let's clean it up to just contain the code below:

```
using System;
using System.Collections.Generic;
using System.Linq;
using Microsoft.VisualStudio.TestTools.UnitTesting;
using NerdDinner.Models;

namespace NerdDinner.Tests.Models {

    [TestClass]
    public class DinnerTest {

    }
}
```

The [TestClass] attribute on the DinnerTest class above identifies it as a class that will contain tests, as well as optional test initialization and teardown code. We can define tests within it by adding public methods that have a [TestMethod] attribute on them.

Below are the first of two tests we'll add that exercise our Dinner class. The first test verifies that our Dinner is invalid if a new Dinner is created without all properties being set correctly. The second test verifies that our Dinner is valid when a Dinner has all properties set with valid values:

```
[TestClass]
public class DinnerTest {

    [TestMethod]
    public void Dinner_Should_Not_Be_Valid_When_Some_Properties_Incorrect() {

        //Arrange
        Dinner dinner = new Dinner() {
            Title = "Test title",
            Country = "USA",
            ContactPhone = "BOGUS"
        };

        // Act
        bool isValid = dinner.IsValid;

        //Assert
        Assert.IsFalse(isValid);
    }

    [TestMethod]
    public void Dinner_Should_Be_Valid_When_All_Properties_Correct() {

        //Arrange
        Dinner dinner = new Dinner {
            Title = "Test title",
            Description = "Some description",
            EventDate = DateTime.Now,
            HostedBy = "ScottGu",
            Address = "One Microsoft Way",
            Country = "USA",
            ContactPhone = "425-703-8072",
            Latitude = 93,
            Longitude = -92,
        };

        // Act
        bool isValid = dinner.IsValid;

        //Assert
        Assert.IsTrue(isValid);
    }
}
```

You'll notice above that our test names are very explicit (and somewhat verbose). We are doing this because we might end up creating hundreds or thousands of small tests, and we want to make it easy to quickly determine the intent and behavior of each of them (especially when we are looking through a list of failures in a test runner). The test names should be named after the functionality they are testing. Above we are using a "Noun_Should_Verb" naming pattern.

We are structuring the tests using the "AAA" testing pattern – which stands for "Arrange, Act, Assert":

- Arrange: Setup the unit being tested
- Act: Exercise the unit under test and capture results
- Assert: Verify the behavior

When we write tests we want to avoid having the individual tests do too much. Instead each test should verify only a single concept (which will make it much easier to pinpoint the cause of failures). A good guideline is to try and only have a single assert statement for each test. If you have more than one assert statement in a test method, make sure they are all being used to test the same concept. When in doubt, make another test.

Running Tests

Visual Studio 2008 Professional (and higher editions) includes a built-in test runner that can be used to run Visual Studio Unit Test projects within the IDE. We can select the **Test->Run->All Tests in Solution** menu command (or type Ctrl R, A) to run all of our unit tests. Or alternatively we can position our cursor within a specific test class or test method and use the **Test->Run->Tests in Current Context** menu command (or type Ctrl R, T) to run a subset of the unit tests.

Let's position our cursor within the DinnerTest class and type "Ctrl R, T" to run the two tests we just defined. When we do this a "Test Results" window will appear within Visual Studio and we'll see the results of our test run listed within it:

Note: The VS test results window does not show the Class Name column by default. You can add this by right-clicking within the Test Results window and using the Add/Remove Columns menu command.

Our two tests took only a fraction of a second to run – and as you can see they both passed. We can now go on and augment them by creating additional tests that verify specific rule validations, as well as cover the two helper methods - IsUserHost() and IsUserRegistered() – that we added to the Dinner class. Having all these tests in place for the Dinner class will make it much easier and safer to add new business rules and validations to it in the future. We can add our new rule logic to Dinner, and then within seconds verify that it hasn't broken any of our previous logic functionality.

Notice how using a descriptive test name makes it easy to quickly understand what each test is verifying. I recommend using the **Tools->Options** menu command, opening the Test Tools->Test Execution configuration screen, and checking the "Double-clicking a failed or inconclusive unit test result displays the point of failure in the test" checkbox. This will allow you to double-click on a failure in the test results window and jump immediately to the assert failure.

Creating DinnersController Unit Tests

Let's now create some unit tests that verify our DinnersController functionality. We'll start by right-clicking on the "Controllers" folder within our Test project and then choose the **Add->New Test** menu command. We'll create a "Unit Test" and name it "DinnersControllerTest.cs".

We'll create two test methods that verify the Details() action method on the DinnersController. The first will verify that a View is returned when an existing Dinner is requested. The second will verify that a "NotFound" view is returned when a non-existent Dinner is requested:

```
[TestClass]
public class DinnersControllerTest {

    [TestMethod]
    public void DetailsAction_Should_Return_View_For_ExistingDinner() {

        // Arrange
        var controller = new DinnersController();

        // Act
        var result = controller.Details(1) as ViewResult;

        // Assert
        Assert.IsNotNull(result, "Expected View");
    }

    [TestMethod]
    public void DetailsAction_Should_Return_NotFoundView_For_BogusDinner() {

        // Arrange
        var controller = new DinnersController();

        // Act
        var result = controller.Details(999) as ViewResult;

        // Assert
        Assert.AreEqual("NotFound", result.ViewName);
    }
}
```

The above code compiles clean. When we run the tests, though, they both fail:

If we look at the error messages, we'll see that the reason the tests failed was because our DinnersRepository class was unable to connect to a database. Our NerdDinner application is using a connection-string to a local SQL Server Express file which lives under the \App_Data directory of the NerdDinner application project. Because our NerdDinner.Tests project compiles and runs in a different directory then the application project, the relative path location of our connection-string is incorrect.

We *could* fix this by copying the SQL Express database file to our test project, and then add an appropriate test connection-string to it in the App.config of our test project. This would get the above tests unblocked and running.

Unit testing code using a real database, though, brings with it a number of challenges. Specifically:

- It significantly slows down the execution time of unit tests. The longer it takes to run tests, the less likely you are to execute them frequently. Ideally you want your unit tests to be able to be run in seconds – and have it be something you do as naturally as compiling the project.
- It complicates the setup and cleanup logic within tests. You want each unit test to be isolated and independent of others (with no side effects or dependencies). When working against a real database you have to be mindful of state and reset it between tests.

Let's look at a design pattern called "dependency injection" that can help us work around these issues and avoid the need to use a real database with our tests.

Dependency Injection

Right now DinnersController is tightly "coupled" to the DinnerRepository class. "Coupling" refers to a situation where a class explicitly relies on another class in order to work:

```
public class DinnersController : Controller {

    DinnerRepository dinnerRepository = new DinnerRepository();

    //
    // GET: /Dinners/Details/5

    public ActionResult Details(int id) {

        Dinner dinner = dinnerRepository.FindDinner(id);

        if (dinner == null)
            return View("NotFound");

        return View(dinner);
    }
```

Because the DinnerRepository class requires access to a database, the tightly coupled dependency the DinnersController class has on the DinnerRepository ends up requiring us to have a database in order for the DinnersController action methods to be tested.

We can get around this by employing a design pattern called "dependency injection" – which is an approach where dependencies (like repository classes that provide data access) are no longer implicitly created within classes that use them. Instead, dependencies can be explicitly passed to the class that uses them using constructor arguments. If the dependencies are defined using interfaces, we then have the flexibility to pass in "fake" dependency implementations for unit test scenarios. This enables us to create test-specific dependency implementations that do not actually require access to a database.

To see this in action, let's implement dependency injection with our DinnersController.

Extracting an IDinnerRepository interface

Our first step will be to create a new IDinnerRepository interface that encapsulates the repository contract our controllers require to retrieve and update Dinners.

We can define this interface contract manually by right-clicking on the \Models folder, and then choosing the **Add->New Item** menu command and creating a new interface named IDinnerRepository.cs.

Alternatively we can use the refactoring tools built-into Visual Studio Professional (and higher editions) to automatically extract and create an interface for us from our existing DinnerRepository class. To extract this interface using VS, simply position the cursor in the text editor on the DinnerRepository class, and then right-click and choose the **Refactor->Extract Interface** menu command:

This will launch the "Extract Interface" dialog and prompt us for the name of the interface to create. It will default to IDinnerRepository and automatically select all public methods on the existing DinnerRepository class to add to the interface:

When we click the "ok" button, Visual Studio will add a new IDinnerRepository interface to our application:

```
public interface IDinnerRepository {

    IQueryable<Dinner> FindAllDinners();
    IQueryable<Dinner> FindByLocation(float latitude, float longitude);
    IQueryable<Dinner> FindUpcomingDinners();
    Dinner             GetDinner(int id);

    void Add(Dinner dinner);
    void Delete(Dinner dinner);

    void Save();
}
```

And our existing DinnerRepository class will be updated so that it implements the interface:

```
public class DinnerRepository : IDinnerRepository {
   ...
}
```

Updating DinnersController to support constructor injection

We'll now update the DinnersController class to use the new interface.

Currently DinnersController is hard-coded such that its "dinnerRepository" field is always a DinnerRepository class:

```
public class DinnersController : Controller {

    DinnerRepository dinnerRepository = new DinnerRepository();

    ...
}
```

We'll change it so that the "dinnerRepository" field is of type IDinnerRepository instead of DinnerRepository. We'll then add two public DinnersController constructors. One of the constructors allows an IDinnerRepository to be

passed as an argument. The other is a default constructor that uses our existing DinnerRepository implementation:

```
public class DinnersController : Controller {

    IDinnerRepository dinnerRepository;

    public DinnersController()
        : this(new DinnerRepository()) {
    }

    public DinnersController(IDinnerRepository repository) {
        dinnerRepository = repository;
    }
    ...
}
```

Because ASP.NET MVC by default creates controller classes using default constructors, our DinnersController at runtime will continue to use the DinnerRepository class to perform data access.

We can now update our unit tests, though, to pass in a "fake" dinner repository implementation using the parameter constructor. This "fake" dinner repository will not require access to a real database, and instead will use in-memory sample data.

Creating the FakeDinnerRepository class

Let's create a FakeDinnerRepository class.

We'll begin by creating a "Fakes" directory within our NerdDinner.Tests project and then add a new FakeDinnerRepository class to it (right-click on the folder and choose **Add->New Class**):

We'll update the code so that the FakeDinnerRepository class implements the IDinnerRepository interface. We can then right-click on it and choose the "Implement interface IDinnerRepository" context menu command:

This will cause Visual Studio to automatically add all of the IDinnerRepository interface members to our FakeDinnerRepository class with default "stub out" implementations:

```
public class FakeDinnerRepository : IDinnerRepository {

    public IQueryable<Dinner> FindAllDinners() {
        throw new NotImplementedException();
    }

    public IQueryable<Dinner> FindByLocation(float lat, float long){
        throw new NotImplementedException();
    }

    public IQueryable<Dinner> FindUpcomingDinners() {
        throw new NotImplementedException();
    }

    public Dinner GetDinner(int id) {
        throw new NotImplementedException();
    }

    public void Add(Dinner dinner) {
        throw new NotImplementedException();
    }

    public void Delete(Dinner dinner) {
        throw new NotImplementedException();
    }

    public void Save() {
        throw new NotImplementedException();
    }
}
```

We can then update the FakeDinnerRepository implementation to work off of an in-memory List<Dinner> collection passed to it as a constructor argument:

```
public class FakeDinnerRepository : IDinnerRepository {

    private List<Dinner> dinnerList;

    public FakeDinnerRepository(List<Dinner> dinners) {
        dinnerList = dinners;
    }

    public IQueryable<Dinner> FindAllDinners() {
        return dinnerList.AsQueryable();
    }

    public IQueryable<Dinner> FindUpcomingDinners() {
        return (from dinner in dinnerList
                where dinner.EventDate > DateTime.Now
                select dinner).AsQueryable();
    }

    public IQueryable<Dinner> FindByLocation(float lat, float lon) {
        return (from dinner in dinnerList
                where dinner.Latitude == lat && dinner.Longitude == lon
                select dinner).AsQueryable();
    }

    public Dinner GetDinner(int id) {
        return dinnerList.SingleOrDefault(d => d.DinnerID == id);
    }

    public void Add(Dinner dinner) {
        dinnerList.Add(dinner);
    }

    public void Delete(Dinner dinner) {
        dinnerList.Remove(dinner);
    }

    public void Save() {
        foreach (Dinner dinner in dinnerList) {
            if (!dinner.IsValid)
                throw new ApplicationException("Rule violations");
        }
    }
}
```

We now have a fake IDinnerRepository implementation that does not require a database, and can instead work off an in-memory list of Dinner objects.

Using the FakeDinnerRepository with Unit Tests

Let's return to the DinnersController unit tests that failed earlier because the database wasn't available. We can update the test methods to use a FakeDinnerRepository populated with sample in-memory Dinner data to the DinnersController using the code below:

```
[TestClass]
public class DinnersControllerTest {

    List<Dinner> CreateTestDinners() {

        List<Dinner> dinners = new List<Dinner>();

        for (int i = 0; i < 101; i++) {

            Dinner sampleDinner = new Dinner() {
                DinnerID = i,
                Title = "Sample Dinner",
                HostedBy = "SomeUser",
                Address = "Some Address",
                Country = "USA",
                ContactPhone = "425-555-1212",
                Description = "Some description",
                EventDate = DateTime.Now.AddDays(i),
                Latitude = 99,
                Longitude = -99
            };

            dinners.Add(sampleDinner);
        }

        return dinners;
    }

    DinnersController CreateDinnersController() {
        var repository = new FakeDinnerRepository(CreateTestDinners());
        return new DinnersController(repository);
    }

    [TestMethod]
    public void DetailsAction_Should_Return_View_For_Dinner() {

        // Arrange
        var controller = CreateDinnersController();

        // Act
        var result = controller.Details(1);

        // Assert
        Assert.IsInstanceOfType(result, typeof(ViewResult));
    }

    [TestMethod]
    public void DetailsAction_Should_Return_NotFoundView_For_BogusDinner() {

        // Arrange
        var controller = CreateDinnersController();

        // Act
        var result = controller.Details(999) as ViewResult;

        // Assert
        Assert.AreEqual("NotFound", result.ViewName);
    }
}
```

And now when we run these tests they both pass:

Test Results

scottgu@SCOTTGU-WIN7 2009-0 | Run | Debug | Group By: [None] | [All Columr

Test run completed Results: 2/2 passed; Item(s) checked: 0

Result	Class Name	Test Name	Duration	Error Messag
Passed	DinnersControllerTest	DetailsAction_Should_Return_NotFoundView_For_BogusDinner	00:00:00.0003707	
Passed	DinnersControllerTest	DetailsAction_Should_Return_View_For_Dinner	00:00:00.0233735	

Best of all, they take only a fraction of a second to run, and do not require any complicated setup/cleanup logic. We can now unit test all of our DinnersController action method code (including listing, paging, details, create, update and delete) without ever needing to connect to a real database.

SIDE TOPIC: DEPENDENCY INJECTION FRAMEWORKS

Performing manual dependency injection (like we are above) works fine, but does become harder to maintain as the number of dependencies and components in an application increases. Several dependency injection frameworks exist for .NET that can help provide even more dependency management flexibility. These frameworks, also sometimes called "Inversion of Control" (IoC) containers, provide mechanisms that enable an additional level of configuration support for specifying and passing dependencies to objects at runtime (most often using constructor injection). Some of the more popular OSS Dependency Injection / IOC frameworks in .NET include: AutoFac, Ninject, Spring.NET, StructureMap, and Windsor. ASP.NET MVC exposes extensibility APIs that enable developers to participate in the resolution and instantiation of controllers, and which enables Dependency Injection / IoC frameworks to be cleanly integrated within this process. Using a DI/IOC framework would also enable us to remove the default constructor from our DinnersController – which would completely remove the coupling between it and the DinnerRepository. We won't be using a dependency injection / IOC framework with our NerdDinner application. But it is something we could consider for the future if the NerdDinner code-base and capabilities grew.

Creating Edit Action Unit Tests

Let's now create some unit tests that verify the Edit functionality of the DinnersController. We'll start by testing the HTTP-GET version of our Edit action:

```
//
// GET: /Dinners/Edit/5

[Authorize]
public ActionResult Edit(int id) {

    Dinner dinner = dinnerRepository.GetDinner(id);

    if (!dinner.IsHostedBy(User.Identity.Name))
        return View("InvalidOwner");

    return View(new DinnerFormViewModel(dinner));
}
```

We'll create a test that verifies that a View backed by a DinnerFormViewModel object is rendered back when a valid dinner is requested:

```
[TestMethod]
public void EditAction_Should_Return_View_For_ValidDinner() {

    // Arrange
    var controller = CreateDinnersController();

    // Act
    var result = controller.Edit(1) as ViewResult;

    // Assert
    Assert.IsInstanceOfType(result.ViewData.Model, typeof(DinnerFormViewModel));
}
```

When we run the test, though, we'll find that it fails because a null reference exception is thrown when the Edit method accesses the User.Identity.Name property to perform the Dinner.IsHostedBy() check.

The User object on the Controller base class encapsulates details about the logged-in user, and is populated by ASP.NET MVC when it creates the controller at runtime. Because we are testing the DinnersController outside of a web-server environment, the User object isn't set (hence the null reference exception).

Mocking the User.Identity.Name property

Mocking frameworks make testing easier by enabling us to dynamically create fake versions of dependent objects that support our tests. For example, we can use a mocking framework in our Edit action test to dynamically create a User object that our DinnersController can use to lookup a simulated username. This will avoid a null reference from being thrown when we run our test.

There are many .NET mocking frameworks that can be used with ASP.NET MVC (you can see a list of them here: http://www.mockframeworks.com/). For testing our NerdDinner application we'll use an open source mocking framework called "Moq", which can be downloaded for free from http://www.mockframeworks.com/moq.

Once downloaded, we'll add a reference in our NerdDinner.Tests project to the Moq.dll assembly:

We'll then add a "CreateDinnersControllerAs(username)" helper method to our test class that takes a username as a parameter, and which then "mocks" the User.Identity.Name property on the DinnersController instance:

```
DinnersController CreateDinnersControllerAs(string userName) {

    var mock = new Mock<ControllerContext>();
    mock.SetupGet(p => p.HttpContext.User.Identity.Name).Returns(userName);
    mock.SetupGet(p => p.HttpContext.Request.IsAuthenticated).Returns(true);

    var controller = CreateDinnersController();
    controller.ControllerContext = mock.Object;

    return controller;
}
```

Above we are using Moq to create a Mock object that fakes a ControllerContext object (which is what ASP.NET MVC passes to Controller classes to expose runtime objects like User, Request, Response, and Session). We are calling the "SetupGet" method on the Mock to indicate that the HttpContext.User.Identity.Name property on

ControllerContext should return the username string we passed to the helper method.

We can mock any number of ControllerContext properties and methods. To illustrate this I've also added a SetupGet() call for the Request.IsAuthenticated property (which isn't actually needed for the tests below – but which helps illustrate how you can mock Request properties). When we are done we assign an instance of the ControllerContext mock to the DinnersController our helper method returns.

We can now write unit tests that use this helper method to test Edit scenarios involving different users:

```
[TestMethod]
public void EditAction_Should_Return_EditView_When_ValidOwner() {

    // Arrange
    var controller = CreateDinnersControllerAs("SomeUser");

    // Act
    var result = controller.Edit(1) as ViewResult;

    // Assert
    Assert.IsInstanceOfType(result.ViewData.Model, typeof(DinnerFormViewModel));
}

[TestMethod]
public void EditAction_Should_Return_InvalidOwnerView_When_InvalidOwner() {

    // Arrange
    var controller = CreateDinnersControllerAs("NotOwnerUser");

    // Act
    var result = controller.Edit(1) as ViewResult;

    // Assert
    Assert.AreEqual(result.ViewName, "InvalidOwner");
}
```

And now when we run the tests they pass:

Testing UpdateModel() scenarios

We've created tests that cover the HTTP-GET version of the Edit action. Let's now create some tests that verify the HTTP-POST version of the Edit action:

```
//
// POST: /Dinners/Edit/5

[AcceptVerbs(HttpVerbs.Post), Authorize]
public ActionResult Edit (int id, FormCollection collection) {

    Dinner dinner = dinnerRepository.GetDinner(id);

    if (!dinner.IsHostedBy(User.Identity.Name))
        return View("InvalidOwner");

    try {
        UpdateModel(dinner);

        dinnerRepository.Save();

        return RedirectToAction("Details", new { id=dinner.DinnerID });
    }
    catch {
        ModelState.AddModelErrors(dinner.GetRuleViolations());

        return View(new DinnerFormViewModel(dinner));
    }
}
```

The interesting new testing scenario for us to support with this action method is its usage of the UpdateModel() helper method on the Controller base class. We are using this helper method to bind form-post values to our Dinner object instance.

Below are two tests that demonstrates how we can supply form posted values for the UpdateModel() helper method to use. We'll do this by creating and populating a FormCollection object, and then assign it to the "ValueProvider" property on the Controller.

The first test verifies that on a successful save the browser is redirected to the details action. The second test verifies that when invalid input is posted the action redisplays the edit view again with an error message.

```
[TestMethod]
public void EditAction_Should_Redirect_When_Update_Successful() {

    // Arrange
    var controller = CreateDinnersControllerAs("SomeUser");

    var formValues = new FormCollection() {
        { "Title", "Another value" },
        { "Description", "Another description" }
    };

    controller.ValueProvider = formValues.ToValueProvider();

    // Act
    var result = controller.Edit(1, formValues) as RedirectToRouteResult;

    // Assert
    Assert.AreEqual("Details", result.RouteValues["Action"]);
}

[TestMethod]
public void EditAction_Should_Redisplay_With_Errors_When_Update_Fails() {

    // Arrange
    var controller = CreateDinnersControllerAs("SomeUser");

    var formValues = new FormCollection() {
        { "EventDate", "Bogus date value!!!"}
    };

    controller.ValueProvider = formValues.ToValueProvider();

    // Act
    var result = controller.Edit(1, formValues) as ViewResult;

    // Assert
    Assert.IsNotNull(result, "Expected redisplay of view");
    Assert.IsTrue(result.ViewData.ModelState.Count > 0, "Expected errors");
}
```

Testing Wrap-Up

We've covered the core concepts involved in unit testing controller classes. We can use these techniques to easily create hundreds of simple tests that verify the behavior of our application.

Because our controller and model tests do not require a real database, they are extremely fast and easy to run. We'll be able to execute hundreds of automated tests in seconds, and immediately get feedback as to whether a change we made broke something. This will help provide us the confidence to continually improve, refactor, and refine our application.

We covered testing as the last topic in this chapter – but not because testing is something you should do at the end of a development process! On the contrary, you should write automated tests as early as possible in your development process. Doing so enables you to get immediate feedback as you develop, helps you think thoughtfully about your application's use case scenarios, and guides you to design your application with clean layering and coupling in mind.

A later chapter in the book will discuss Test Driven Development (TDD), and how to use it with ASP.NET MVC. TDD is an iterative coding practice where you first write the tests that your resulting code will satisfy. With TDD you begin each feature by creating a test that verifies the functionality you are about to implement. Writing the unit test first helps ensure that you clearly understand the feature and how it is supposed to work. Only after the test is written (and you have verified that it fails) do you then implement the actual functionality the test verifies. Because you've already spent time thinking about the use case of how the feature is supposed to work, you will have a

better understanding of the requirements and how best to implement them. When you are done with the implementation you can re-run the test – and get immediate feedback as to whether the feature works correctly. We'll cover TDD more in Chapter 10.

Next Step

Some final wrap up comments.

NerdDinner Wrap Up

4/10/2020 • 2 minutes to read • Edit Online

by Microsoft

Download PDF

> This is the conclusion of the NerdDinner tutorial, and provides you with information on how to learn more.
>
> If you are using ASP.NET MVC 3, we recommend you follow the Getting Started With MVC 3 or MVC Music Store tutorials.

Our NerdDinner application is now complete and ready to deploy on the web.

We used a broad set of ASP.NET MVC features to build NerdDinner. Hopefully the process of developing it shed some light on how the core ASP.NET MVC features work, and provided context on how these features integrate together within an application.

Learning More

This NerdDinner tutorial is the first chapter of the new Professional ASP.NET MVC 1.0 book from Wrox Press.

You can read the rest of the book to learn even more about ASP.NET MVC.

You can also find great ASP.NET MVC tutorials and videos at: https://www.asp.net/mvc Other great ASP.NET MVC books will shortly be published. I will update this page to include links to additional books as they become available.

Hope this helps,

Scott

Create a Movie Database Application in 15 Minutes with ASP.NET MVC (C#)

2/20/2020 • 17 minutes to read • Edit Online

by Stephen Walther

Download Code

> Stephen Walther builds an entire database-driven ASP.NET MVC application from start to finish. This tutorial is a great introduction for people who are new to the ASP.NET MVC Framework and who want to get a sense of the process of building an ASP.NET MVC application.

The purpose of this tutorial is to give you a sense of "what it is like" to build an ASP.NET MVC application. In this tutorial, I blast through building an entire ASP.NET MVC application from start to finish. I show you how to build a simple database-driven application that illustrates how you can list, create, and edit database records.

To simplify the process of building our application, we'll take advantage of the scaffolding features of Visual Studio 2008. We'll let Visual Studio generate the initial code and content for our controllers, models, and views.

If you have worked with Active Server Pages or ASP.NET, then you should find ASP.NET MVC very familiar. ASP.NET MVC views are very much like the pages in an Active Server Pages application. And, just like a traditional ASP.NET Web Forms application, ASP.NET MVC provides you with full access to the rich set of languages and classes provided by the .NET framework.

My hope is that this tutorial will give you a sense of how the experience of building an ASP.NET MVC application is both similar and different than the experience of building an Active Server Pages or ASP.NET Web Forms application.

Overview of the Movie Database Application

Because our goal is to keep things simple, we'll build a very simple Movie Database application. Our simple Movie Database application will allow us to do three things:

1. List a set of movie database records
2. Create a new movie database record
3. Edit an existing movie database record

Again, because we want to keep things simple, we'll take advantage of the minimum number of features of the ASP.NET MVC framework needed to build our application. For example, we won't be taking advantage of Test-Driven Development.

In order to create our application, we need to complete each of the following steps:

1. Create the ASP.NET MVC Web Application Project
2. Create the database
3. Create the database model
4. Create the ASP.NET MVC controller
5. Create the ASP.NET MVC views

Preliminaries

You'll need either Visual Studio 2008 or Visual Web Developer 2008 Express to build an ASP.NET MVC application. You also need to download the ASP.NET MVC framework.

If you don't own Visual Studio 2008, then you can download a 90 day trial version of Visual Studio 2008 from this website:

https://msdn.microsoft.com/vs2008/products/cc268305.aspx

Alternatively, you can create ASP.NET MVC applications with Visual Web Developer Express 2008. If you decide to use Visual Web Developer Express then you must have Service Pack 1 installed. You can download Visual Web Developer 2008 Express with Service Pack 1 from this website:

https://www.microsoft.com/downloads/details.aspx?FamilyId=BDB6391C-05CA-4036-9154-6DF4F6DEBD14&displaylang=en

After you install either Visual Studio 2008 or Visual Web Developer 2008, you need to install the ASP.NET MVC framework. You can download the ASP.NET MVC framework from the following website:

https://www.asp.net/mvc/

NOTE

Instead of downloading the ASP.NET framework and the ASP.NET MVC framework individually, you can take advantage of the Web Platform Installer. The Web Platform Installer is an application that enables you to easily manage the installed applications are your computer:

https://www.microsoft.com/web/gallery/Install.aspx

Creating an ASP.NET MVC Web Application Project

Let's start by creating a new ASP.NET MVC Web Application project in Visual Studio 2008. Select the menu option **File, New Project** and you will see the New Project dialog box in Figure 1. Select C# as the programming language and select the ASP.NET MVC Web Application project template. Give your project the name MovieApp and click the OK button.

Figure 01: The New Project dialog box (Click to view full-size image)

Make sure that you select .NET Framework 3.5 from the dropdown list at the top of the New Project dialog or the

ASP.NET MVC Web Application project template won't appear.

Whenever you create a new MVC Web Application project, Visual Studio prompts you to create a separate unit test project. The dialog in Figure 2 appears. Because we won't be creating tests in this tutorial because of time constraints (and, yes, we should feel a little guilty about this) select the **No** option and click the **OK** button.

> **NOTE**
> Visual Web Developer does not support test projects.

Figure 02: The Create Unit Test Project dialog (Click to view full-size image)

An ASP.NET MVC application has a standard set of folders: a Models, Views, and Controllers folder. You can see this standard set of folders in the Solution Explorer window. We'll need to add files to each of the Models, Views, and Controllers folders in order to build our Movie Database application.

When you create a new MVC application with Visual Studio, you get a sample application. Because we want to start from scratch, we need to delete the content for this sample application. You need to delete the following file and the following folder:

- Controllers\HomeController.cs
- Views\Home

Creating the Database

We need to create a database to hold our movie database records. Luckily, Visual Studio includes a free database named SQL Server Express. Follow these steps to create the database:

1. Right-click the App_Data folder in the Solution Explorer window and select the menu option **Add, New Item**.
2. Select the **Data** category and select the **SQL Server Database** template (see Figure 3).
3. Name your new database *MoviesDB.mdf* and click the **Add** button.

After you create your database, you can connect to the database by double-clicking the MoviesDB.mdf file located in the App_Data folder. Double-clicking the MoviesDB.mdf file opens the Server Explorer window.

> **NOTE**
> The Server Explorer window is named the Database Explorer window in the case of Visual Web Developer.

Figure 03: Creating a Microsoft SQL Server Database (Click to view full-size image)

Next, we need to create a new database table. From within the Sever Explorer window, right-click the Tables folder and select the menu option **Add New Table**. Selecting this menu option opens the database table designer. Create the following database columns:

COLUMN NAME	DATA TYPE	ALLOW NULLS
Id	Int	False
Title	Nvarchar(100)	False
Director	Nvarchar(100)	False
DateReleased	DateTime	False

The first column, the Id column, has two special properties. First, you need to mark the Id column as the primary key column. After selecting the Id column, click the **Set Primary Key** button (it is the icon that looks like a key). Second, you need to mark the Id column as an Identity column. In the Column Properties window, scroll down to the Identity Specification section and expand it. Change the **Is Identity** property to the value **Yes**. When you are finished, the table should look like Figure 4.

Figure 04: The Movies database table (Click to view full-size image)

The final step is to save the new table. Click the Save button (the icon of the floppy) and give the new table the name Movies.

After you finish creating the table, add some movie records to the table. Right-click the Movies table in the Server Explorer window and select the menu option **Show Table Data**. Enter a list of your favorite movies (see Figure 5).

Figure 05: Entering movie records (Click to view full-size image)

Creating the Model

We next need to create a set of classes to represent our database. We need to create a database model. We'll take advantage of the Microsoft Entity Framework to generate the classes for our database model automatically.

> **NOTE**
> The ASP.NET MVC framework is not tied to the Microsoft Entity Framework. You can create your database model classes by taking advantage of a variety of Object Relational Mapping (OR/M) tools including LINQ to SQL, Subsonic, and NHibernate.

Follow these steps to launch the Entity Data Model Wizard:

1. Right-click the Models folder in the Solution Explorer window and the select the menu option **Add, New Item**.
2. Select the **Data** category and select the **ADO.NET Entity Data Model** template.
3. Give your data model the name *MoviesDBModel.edmx* and click the **Add** button.

After you click the Add button, the Entity Data Model Wizard appears (see Figure 6). Follow these steps to complete the wizard:

1. In the **Choose Model Contents** step, select the **Generate from database** option.
2. In the **Choose Your Data Connection** step, use the *MoviesDB.mdf* data connection and the name *MoviesDBEntities* for the connection settings. Click the **Next** button.
3. In the **Choose Your Database Objects** step, expand the Tables node, select the Movies table. Enter the namespace *MovieApp.Models* and click the **Finish** button.

Figure 06: Generating a database model with the Entity Data Model Wizard (Click to view full-size image)

After you complete the Entity Data Model Wizard, the Entity Data Model Designer opens. The Designer should display the Movies database table (see Figure 7).

Figure 07: The Entity Data Model Designer (Click to view full-size image)

We need to make one change before we continue. The Entity Data Wizard generates a model class named *Movies* that represents the Movies database table. Because we'll use the Movies class to represent a particular movie, we need to modify the name of the class to be *Movie* instead of *Movies* (singular rather than plural).

Double-click the name of the class on the designer surface and change the name of the class from Movies to Movie. After making this change, click the **Save** button (the icon of the floppy disk) to generate the Movie class.

Creating the ASP.NET MVC Controller

The next step is to create the ASP.NET MVC controller. A controller is responsible for controlling how a user interacts with an ASP.NET MVC application.

Follow these steps:

1. In the Solution Explorer window, right-click the Controllers folder and select the menu option **Add, Controller**.
2. In the Add Controller dialog, enter the name *HomeController* and check the checkbox labeled **Add action methods for Create, Update, and Details scenarios** (see Figure 8).
3. Click the **Add** button to add the new controller to your project.

After you complete these steps, the controller in Listing 1 is created. Notice that it contains methods named Index, Details, Create, and Edit. In the following sections, we'll add the necessary code to get these methods to work.

Figure 08: Adding a new ASP.NET MVC Controller (Click to view full-size image)

Listing 1 – Controllers\HomeController.cs

```
using System;

using System.Collections.Generic;

using System.Linq;

using System.Web;

using System.Web.Mvc;

using System.Web.Mvc.Ajax;

namespace MovieApp.Controllers

{

    public class HomeController : Controller

    {

        //

        // GET: /Home/

        public ActionResult Index()

        {

            return View();

        }

        //

        // GET: /Home/Details/5

        public ActionResult Details(int id)

        {

            return View();

        }

        //

        // GET: /Home/Create

        public ActionResult Create()

        {

            return View();

        }

        //

        // POST: /Home/Create

        [AcceptVerbs(HttpVerbs.Post)]

        public ActionResult Create(FormCollection collection)

        {

            try
```

```
            {
                // TODO: Add insert logic here
                return RedirectToAction("Index");
            }
            catch
            {
                return View();
            }
        }
        //
        // GET: /Home/Edit/5
        public ActionResult Edit(int id)
        {
            return View();
        }
        //
        // POST: /Home/Edit/5
        [AcceptVerbs(HttpVerbs.Post)]
        public ActionResult Edit(int id, FormCollection collection)
        {
            try
            {
                // TODO: Add update logic here
                return RedirectToAction("Index");
            }
            catch
            {
                return View();
            }
        }
    }
}
```

Listing Database Records

The Index() method of the Home controller is the default method for an ASP.NET MVC application. When you run an ASP.NET MVC application, the Index() method is the first controller method that is called.

We'll use the Index() method to display the list of records from the Movies database table. We'll take advantage of the database model classes that we created earlier to retrieve the movie database records with the Index() method.

I've modified the HomeController class in Listing 2 so that it contains a new private field named _db. The MoviesDBEntities class represents our database model and we'll use this class to communicate with our database.

I've also modified the Index() method in Listing 2. The Index() method uses the MoviesDBEntities class to retrieve all of the movie records from the Movies database table. The expression *_db.MovieSet.ToList()* returns a list of all of the movie records from the Movies database table.

The list of movies is passed to the view. Anything that gets passed to the View() method gets passed to the view as view data.

Listing 2 – Controllers/HomeController.cs (modified Index method)

```
using System.Linq;

using System.Web.Mvc;

using MovieApp.Models;

namespace MovieApp.Controllers

{

    public class HomeController : Controller

    {

        private MoviesDBEntities _db = new MoviesDBEntities();

        public ActionResult Index()

        {

            return View(_db.MovieSet.ToList());

        }

    }

}
```

The Index() method returns a view named Index. We need to create this view to display the list of movie database records. Follow these steps:

You should build your project (select the menu option **Build, Build Solution**) before opening the **Add View** dialog or no classes will appear in the **View data class** dropdown list.

1. Right-click the Index() method in the code editor and select the menu option **Add View** (see Figure 9).
2. In the Add View dialog, verify that the checkbox labeled **Create a strongly-typed view** is checked.
3. From the **View content** dropdown list, select the value *List*.
4. From the **View data class** dropdown list, select the value *MovieApp.Models.Movie*.
5. Click the Add button to create the new view (see Figure 10).

After you complete these steps, a new view named Index.aspx is added to the Views\Home folder. The contents of the Index view are included in Listing 3.

Figure 09: Adding a view from a controller action (Click to view full-size image)

Figure 10: Creating a new view with the Add View dialog (Click to view full-size image)

Listing 3 – Views\Home\Index.aspx

```
<%@ Page Title="" Language="C#" MasterPageFile="~/Views/Shared/Site.Master"
Inherits="System.Web.Mvc.ViewPage<IEnumerable<MovieApp.Models.Movie>>" %>

    <asp:Content ID="Content1" ContentPlaceHolderID="TitleContent" runat="server">

       Index

    </asp:Content>

    <asp:Content ID="Content2" ContentPlaceHolderID="MainContent" runat="server">

        <h2>Index</h2>

        <table>
```

```
            <tr>
                <th></th>
                <th>
                    Id
                </th>
                <th>
                    Title
                </th>
                <th>
                    Director
                </th>
                <th>
                    DateReleased
                </th>
            </tr>
        <% foreach (var item in Model) { %>
            <tr>
                <td>
                    <%= Html.ActionLink("Edit", "Edit", new { id=item.Id }) %> |
                    <%= Html.ActionLink("Details", "Details", new { id=item.Id })%>
                </td>
                <td>
                    <%= Html.Encode(item.Id) %>
                </td>
                <td>
                    <%= Html.Encode(item.Title) %>
                </td>
                <td>
                    <%= Html.Encode(item.Director) %>
                </td>
                <td>
                    <%= Html.Encode(String.Format("{0:g}", item.DateReleased)) %>
                </td>
            </tr>
        <% } %>
```

```
        %> }%>

        </table>

        <p>

            <%= Html.ActionLink("Create New", "Create") %>

        </p>

    </asp:Content>
```

The Index view displays all of the movie records from the Movies database table within an HTML table. The view contains a foreach loop that iterates through each movie represented by the ViewData.Model property. If you run your application by hitting the F5 key, then you'll see the web page in Figure 11.

Figure 11: The Index view (Click to view full-size image)

Creating New Database Records

The Index view that we created in the previous section includes a link for creating new database records. Let's go ahead and implement the logic and create the view necessary for creating new movie database records.

The Home controller contains two methods named Create(). The first Create() method has no parameters. This overload of the Create() method is used to display the HTML form for creating a new movie database record.

The second Create() method has a FormCollection parameter. This overload of the Create() method is called when the HTML form for creating a new movie is posted to the server. Notice that this second Create() method has an AcceptVerbs attribute that prevents the method from being called unless an HTTP POST operation is performed.

This second Create() method has been modified in the updated HomeController class in Listing 4. The new version of the Create() method accepts a Movie parameter and contains the logic for inserting a new movie into the Movies database table.

> **NOTE**
>
> Notice the Bind attribute. Because we don't want to update the Movie Id property from HTML form, we need to explicitly exclude this property.

Listing 4 – Controllers\HomeController.cs (modified Create method)

```
//

// GET: /Home/Create

public ActionResult Create()

{

    return View();

}

//

// POST: /Home/Create

[AcceptVerbs(HttpVerbs.Post)]

public ActionResult Create([Bind(Exclude="Id")] Movie movieToCreate)

{

     if (!ModelState.IsValid)

        return View();

    _db.AddToMovieSet(movieToCreate);

    _db.SaveChanges();

    return RedirectToAction("Index");

}
```

Visual Studio makes it easy to create the form for creating a new movie database record (see Figure 12). Follow these steps:

1. Right-click the Create() method in the code editor and select the menu option **Add View**.
2. Verify that the checkbox labeled **Create a strongly-typed view** is checked.
3. From the **View content** dropdown list, select the value *Create*.
4. From the **View data class** dropdown list, select the value *MovieApp.Models.Movie*.
5. Click the **Add** button to create the new view.

Figure 12: Adding the Create view (Click to view full-size image)

Visual Studio generates the view in Listing 5 automatically. This view contains an HTML form that includes fields that correspond to each of the properties of the Movie class.

Listing 5 – Views\Home\Create.aspx

```
<%@ Page Title="" Language="C#" MasterPageFile="~/Views/Shared/Site.Master"
Inherits="System.Web.Mvc.ViewPage<MovieApp.Models.Movie>" %>

    <asp:Content ID="Content1" ContentPlaceHolderID="TitleContent" runat="server">

       Create

    </asp:Content>

    <asp:Content ID="Content2" ContentPlaceHolderID="MainContent" runat="server">

        <h2>Create</h2>

        <%= Html.ValidationSummary("Create was unsuccessful. Please correct the errors and try again.") %>

        <% using (Html.BeginForm()) {%>

            <fieldset>

                <legend>Fields</legend>

                <p>

                    <label for="Id">Id:</label>

                    <%= Html.TextBox("Id") %>

                    <%= Html.ValidationMessage("Id", "*") %>

                </p>

                <p>

                    <label for="Title">Title:</label>

                    <%= Html.TextBox("Title") %>

                    <%= Html.ValidationMessage("Title", "*") %>

                </p>

                <p>

                    <label for="Director">Director:</label>

                    <%= Html.TextBox("Director") %>

                    <%= Html.ValidationMessage("Director", "*") %>

                </p>

                <p>

                    <label for="DateReleased">DateReleased:</label>

                    <%= Html.TextBox("DateReleased") %>

                    <%= Html.ValidationMessage("DateReleased", "*") %>

                </p>
```

```
                <p>
                    <input type="submit" value="Create" />
                </p>
            </fieldset>
        <% } %>
        <div>
            <%=Html.ActionLink("Back to List", "Index") %>
        </div>
    </asp:Content>
```

NOTE

The HTML form generated by the Add View dialog generates an Id form field. Because the Id column is an Identity column, we don't need this form field and you can safely remove it.

After you add the Create view, you can add new Movie records to the database. Run your application by pressing the F5 key and click the Create New link to see the form in Figure 13. If you complete and submit the form, a new movie database record is created.

Notice that you get form validation automatically. If you neglect to enter a release date for a movie, or you enter an invalid release date, then the form is redisplayed and the release date field is highlighted.

Figure 13: Creating a new movie database record (Click to view full-size image)

Editing Existing Database Records

In the previous sections, we discussed how you can list and create new database records. In this final section, we discuss how you can edit existing database records.

First, we need to generate the Edit form. This step is easy since Visual Studio will generate the Edit form for us automatically. Open the HomeController.cs class in the Visual Studio code editor and follow these steps:

1. Right-click the Edit() method in the code editor and select the menu option **Add View** (see Figure 14).
2. Check the checkbox labeled **Create a strongly-typed view**.
3. From the **View content** dropdown list, select the value *Edit*.
4. From the **View data class** dropdown list, select the value *MovieApp.Models.Movie*.
5. Click the **Add** button to create the new view.

Completing these steps adds a new view named Edit.aspx to the Views\Home folder. This view contains an HTML form for editing a movie record.

Figure 14: Adding the Edit view (Click to view full-size image)

> **NOTE**
> The Edit view contains an HTML form field that corresponds to the Movie Id property. Because you don't want people editing the value of the Id property, you should remove this form field.

Finally, we need to modify the Home controller so that it supports editing a database record. The updated HomeController class is contained in Listing 6.

Listing 6 – Controllers\HomeController.cs (Edit methods)

```
//

// GET: /Home/Edit/5

public ActionResult Edit(int id)

{

    var movieToEdit = (from m in _db.MovieSet

                       where m.Id == id

                       select m).First();

    return View(movieToEdit);

}

//

// POST: /Home/Edit/5

[AcceptVerbs(HttpVerbs.Post)]

public ActionResult Edit(Movie movieToEdit)

{

    var originalMovie = (from m in _db.MovieSet

                         where m.Id == movieToEdit.Id

                         select m).First();

    if (!ModelState.IsValid)

        return View(originalMovie);

        _db.ApplyPropertyChanges(originalMovie.EntityKey.EntitySetName, movieToEdit);

        _db.SaveChanges();

        return RedirectToAction("Index");

}
```

In Listing 6, I've added additional logic to both overloads of the Edit() method. The first Edit() method returns the movie database record that corresponds to the Id parameter passed to the method. The second overload performs the updates to a movie record in the database.

Notice that you must retrieve the original movie, and then call ApplyPropertyChanges(), to update the existing movie in the database.

Summary

The purpose of this tutorial was to give you a sense of the experience of building an ASP.NET MVC application. I hope that you discovered that building an ASP.NET MVC web application is very similar to the experience of building an Active Server Pages or ASP.NET application.

In this tutorial, we examined only the most basic features of the ASP.NET MVC framework. In future tutorials, we dive deeper into topics such as controllers, controller actions, views, view data, and HTML helpers.

NEXT

Create a Movie Database Application in 15 Minutes with ASP.NET MVC (VB)

2/20/2020 • 17 minutes to read • Edit Online

by Stephen Walther

Download Code

> Stephen Walther builds an entire database-driven ASP.NET MVC application from start to finish. This tutorial is a great introduction for people who are new to the ASP.NET MVC Framework and who want to get a sense of the process of building an ASP.NET MVC application.

The purpose of this tutorial is to give you a sense of "what it is like" to build an ASP.NET MVC application. In this tutorial, I blast through building an entire ASP.NET MVC application from start to finish. I show you how to build a simple database-driven application that illustrates how you can list, create, and edit database records.

To simplify the process of building our application, we'll take advantage of the scaffolding features of Visual Studio 2008. We'll let Visual Studio generate the initial code and content for our controllers, models, and views.

If you have worked with Active Server Pages or ASP.NET, then you should find ASP.NET MVC very familiar. ASP.NET MVC views are very much like the pages in an Active Server Pages application. And, just like a traditional ASP.NET Web Forms application, ASP.NET MVC provides you with full access to the rich set of languages and classes provided by the .NET framework.

My hope is that this tutorial will give you a sense of how the experience of building an ASP.NET MVC application is both similar and different than the experience of building an Active Server Pages or ASP.NET Web Forms application.

Overview of the Movie Database Application

Because our goal is to keep things simple, we'll build a very simple Movie Database application. Our simple Movie Database application will allow us to do three things:

1. List a set of movie database records
2. Create a new movie database record
3. Edit an existing movie database record

Again, because we want to keep things simple, we'll take advantage of the minimum number of features of the ASP.NET MVC framework needed to build our application. For example, we won't be taking advantage of Test-Driven Development.

In order to create our application, we need to complete each of the following steps:

1. Create the ASP.NET MVC Web Application Project
2. Create the database
3. Create the database model
4. Create the ASP.NET MVC controller
5. Create the ASP.NET MVC views

Preliminaries

You'll need either Visual Studio 2008 or Visual Web Developer 2008 Express to build an ASP.NET MVC application. You also need to download the ASP.NET MVC framework.

If you don't own Visual Studio 2008, then you can download a 90 day trial version of Visual Studio 2008 from this website:

https://msdn.microsoft.com/vs2008/products/cc268305.aspx

Alternatively, you can create ASP.NET MVC applications with Visual Web Developer Express 2008. If you decide to use Visual Web Developer Express then you must have Service Pack 1 installed. You can download Visual Web Developer 2008 Express with Service Pack 1 from this website:

https://www.microsoft.com/downloads/details.aspx?FamilyId=BDB6391C-05CA-4036-9154-6DF4F6DEBD14&displaylang=en

After you install either Visual Studio 2008 or Visual Web Developer 2008, you need to install the ASP.NET MVC framework. You can download the ASP.NET MVC framework from the following website:

https://www.asp.net/mvc/

> **NOTE**
>
> Instead of downloading the ASP.NET framework and the ASP.NET MVC framework individually, you can take advantage of the Web Platform Installer. The Web Platform Installer is an application that enables you to easily manage the installed applications are your computer:
>
> https://www.microsoft.com/web/gallery/Install.aspx

Creating an ASP.NET MVC Web Application Project

Let's start by creating a new ASP.NET MVC Web Application project in Visual Studio 2008. Select the menu option **File, New Project** and you will see the New Project dialog box in Figure 1. Select Visual Basic as the programming language and select the ASP.NET MVC Web Application project template. Give your project the name MovieApp and click the OK button.

Figure 01: The New Project dialog box (Click to view full-size image)

Make sure that you select .NET Framework 3.5 from the dropdown list at the top of the New Project dialog or the ASP.NET MVC Web Application project template won't appear.

Whenever you create a new MVC Web Application project, Visual Studio prompts you to create a separate unit test project. The dialog in Figure 2 appears. Because we won't be creating tests in this tutorial because of time constraints (and, yes, we should feel a little guilty about this) select the **No** option and click the **OK** button.

NOTE

Visual Web Developer does not support test projects.

Figure 02: The Create Unit Test Project dialog (Click to view full-size image)

An ASP.NET MVC application has a standard set of folders: a Models, Views, and Controllers folder. You can see this standard set of folders in the Solution Explorer window. We'll need to add files to each of the Models, Views, and Controllers folders in order to build our Movie Database application.

When you create a new MVC application with Visual Studio, you get a sample application. Because we want to start from scratch, we need to delete the content for this sample application. You need to delete the following file and the following folder:

- Controllers\HomeController.vb
- Views\Home

Creating the Database

We need to create a database to hold our movie database records. Luckily, Visual Studio includes a free database named SQL Server Express. Follow these steps to create the database:

1. Right-click the App_Data folder in the Solution Explorer window and select the menu option **Add, New Item**.
2. Select the **Data** category and select the **SQL Server Database** template (see Figure 3).
3. Name your new database *MoviesDB.mdf* and click the **Add** button.

After you create your database, you can connect to the database by double-clicking the MoviesDB.mdf file located in the App_Data folder. Double-clicking the MoviesDB.mdf file opens the Server Explorer window.

NOTE

The Server Explorer window is named the Database Explorer window in the case of Visual Web Developer.

Figure 03: Creating a Microsoft SQL Server Database (Click to view full-size image)

Next, we need to create a new database table. From within the Sever Explorer window, right-click the Tables folder and select the menu option **Add New Table**. Selecting this menu option opens the database table designer. Create the following database columns:

COLUMN NAME	DATA TYPE	ALLOW NULLS
Id	Int	False
Title	Nvarchar(100)	False
Director	Nvarchar(100)	False
DateReleased	DateTime	False

The first column, the Id column, has two special properties. First, you need to mark the Id column as the primary key column. After selecting the Id column, click the **Set Primary Key** button (it is the icon that looks like a key). Second, you need to mark the Id column as an Identity column. In the Column Properties window, scroll down to the Identity Specification section and expand it. Change the **Is Identity** property to the value **Yes**. When you are finished, the table should look like Figure 4.

Figure 04: The Movies database table (Click to view full-size image)

The final step is to save the new table. Click the Save button (the icon of the floppy) and give the new table the name Movies.

After you finish creating the table, add some movie records to the table. Right-click the Movies table in the Server Explorer window and select the menu option **Show Table Data**. Enter a list of your favorite movies (see Figure 5).

Figure 05: Entering movie records (Click to view full-size image)

Creating the Model

We next need to create a set of classes to represent our database. We need to create a database model. We'll take advantage of the Microsoft Entity Framework to generate the classes for our database model automatically.

> **NOTE**
> The ASP.NET MVC framework is not tied to the Microsoft Entity Framework. You can create your database model classes by taking advantage of a variety of Object Relational Mapping (OR/M) tools including LINQ to SQL, Subsonic, and NHibernate.

Follow these steps to launch the Entity Data Model Wizard:

1. Right-click the Models folder in the Solution Explorer window and the select the menu option **Add, New Item**.
2. Select the **Data** category and select the **ADO.NET Entity Data Model** template.
3. Give your data model the name *MoviesDBModel.edmx* and click the **Add** button.

After you click the Add button, the Entity Data Model Wizard appears (see Figure 6). Follow these steps to complete the wizard:

1. In the **Choose Model Contents** step, select the **Generate from database** option.
2. In the **Choose Your Data Connection** step, use the *MoviesDB.mdf* data connection and the name *MoviesDBEntities* for the connection settings. Click the **Next** button.
3. In the **Choose Your Database Objects** step, expand the Tables node, select the Movies table. Enter the namespace *MovieApp.Models* and click the **Finish** button.

Figure 06: Generating a database model with the Entity Data Model Wizard (Click to view full-size image)

After you complete the Entity Data Model Wizard, the Entity Data Model Designer opens. The Designer should display the Movies database table (see Figure 7).

Figure 07: The Entity Data Model Designer (Click to view full-size image)

We need to make one change before we continue. The Entity Data Wizard generates a model class named Movies that represents the Movies database table. Because we'll use the Movies class to represent a particular movie, we need to modify the name of the class to be *Movie* instead of *Movies* (singular rather than plural).

Double-click the name of the class on the designer surface and change the name of the class from Movies to Movie. After making this change, click the **Save** button (the icon of the floppy disk) to generate the Movie class.

Creating the ASP.NET MVC Controller

The next step is to create the ASP.NET MVC controller. A controller is responsible for controlling how a user interacts with an ASP.NET MVC application.

Follow these steps:

1. In the Solution Explorer window, right-click the Controllers folder and select the menu option **Add, Controller**.
2. In the Add Controller dialog, enter the name *HomeController* and check the checkbox labeled **Add action methods for Create, Update, and Details scenarios** (see Figure 8).
3. Click the **Add** button to add the new controller to your project.

After you complete these steps, the controller in Listing 1 is created. Notice that it contains methods named Index, Details, Create, and Edit. In the following sections, we'll add the necessary code to get these methods to work.

Figure 08: Adding a new ASP.NET MVC Controller (Click to view full-size image)

Listing 1 – Controllers\HomeController.vb

```
Public Class HomeController

        Inherits System.Web.Mvc.Controller

        '

        ' GET: /Home/

        Function Index() As ActionResult

            Return View()

        End Function

        '

        ' GET: /Home/Details/5

        Function Details(ByVal id As Integer) As ActionResult

            Return View()

        End Function

        '

        ' GET: /Home/Create

        Function Create() As ActionResult

            Return View()

        End Function

        '

        ' POST: /Home/Create

        <AcceptVerbs(HttpVerbs.Post)> _

        Function Create(ByVal collection As FormCollection) As ActionResult

            Try

                ' TODO: Add insert logic here

                Return RedirectToAction("Index")

            Catch

                Return View()

            End Try

        End Function

        '

        ' GET: /Home/Edit/5

        Function Edit(ByVal id As Integer) As ActionResult

            Return View()

        End Function

        '
```

```
        ' POST: /Home/Edit/5

        <AcceptVerbs(HttpVerbs.Post)> _

        Function Edit(ByVal id As Integer, ByVal collection As FormCollection) As ActionResult

            Try

                ' TODO: Add update logic here

                Return RedirectToAction("Index")

            Catch

                Return View()

            End Try

        End Function

    End Class
```

Listing Database Records

The Index() method of the Home controller is the default method for an ASP.NET MVC application. When you run an ASP.NET MVC application, the Index() method is the first controller method that is called.

We'll use the Index() method to display the list of records from the Movies database table. We'll take advantage of the database model classes that we created earlier to retrieve the movie database records with the Index() method.

I've modified the HomeController class in Listing 2 so that it contains a new private field named _db. The MoviesDBEntities class represents our database model and we'll use this class to communicate with our database.

I've also modified the Index() method in Listing 2. The Index() method uses the MoviesDBEntities class to retrieve all of the movie records from the Movies database table. The expression *_db.MovieSet.ToList()* returns a list of all of the movie records from the Movies database table.

The list of movies is passed to the view. Anything that gets passed to the View() method gets passed to the view as view data.

Listing 2 – Controllers/HomeController.vb (modified Index method)

```
Public Class HomeController

        Inherits System.Web.Mvc.Controller

        Private _db As New MoviesDBEntities()

        Function Index() As ActionResult

            Return View(_db.MovieSet.ToList())

        End Function

    End Class
```

The Index() method returns a view named Index. We need to create this view to display the list of movie database records. Follow these steps:

You should build your project (select the menu option **Build, Build Solution**) before opening the **Add View** dialog or no classes will appear in the **View data class** dropdown list.

1. Right-click the Index() method in the code editor and select the menu option **Add View** (see Figure 9).
2. In the Add View dialog, verify that the checkbox labeled **Create a strongly-typed view** is checked.
3. From the **View content** dropdown list, select the value *List*.
4. From the **View data class** dropdown list, select the value *MovieApp.Movie*.
5. Click the Add button to create the new view (see Figure 10).

After you complete these steps, a new view named Index.aspx is added to the Views\Home folder. The contents of the Index view are included in Listing 3.

Figure 09: Adding a view from a controller action (Click to view full-size image)

Figure 10: Creating a new view with the Add View dialog (Click to view full-size image)

```
<%@ Page Title="" Language="VB" MasterPageFile="~/Views/Shared/Site.Master"
Inherits="System.Web.Mvc.ViewPage(Of IEnumerable (Of MovieApp.Movie))" %>

    <asp:Content ID="Content1" ContentPlaceHolderID="TitleContent" runat="server">

        Index

    </asp:Content>

    <asp:Content ID="Content2" ContentPlaceHolderID="MainContent" runat="server">
```

```
        <h2>Index</h2>

        <p>

            <%=Html.ActionLink("Create New", "Create")%>

        </p>

        <table>

            <tr>

                <th></th>

                <th>

                    Id

                </th>

                <th>

                    Title

                </th>

                <th>

                    Director

                </th>

                <th>

                    DateReleased

                </th>

            </tr>

        <% For Each item In Model%>

            <tr>

                <td>

                    <%=Html.ActionLink("Edit", "Edit", New With {.id = item.Id})%> |

                    <%=Html.ActionLink("Details", "Details", New With {.id = item.Id})%>

                </td>

                <td>

                    <%= Html.Encode(item.Id) %>

                </td>

                <td>

                    <%= Html.Encode(item.Title) %>

                </td>

                <td>

                    <%= Html.Encode(item.Director) %>

                </td>
```

```
                <td>
                    <%= Html.Encode(String.Format("{0:g}", item.DateReleased)) %>
                </td>
            </tr>
        <% Next%>
        </table>
    </asp:Content>
```

The Index view displays all of the movie records from the Movies database table within an HTML table. The view contains a For Each loop that iterates through each movie represented by the ViewData.Model property. If you run your application by hitting the F5 key, then you'll see the web page in Figure 11.

Figure 11: The Index view (Click to view full-size image)

Creating New Database Records

The Index view that we created in the previous section includes a link for creating new database records. Let's go ahead and implement the logic and create the view necessary for creating new movie database records.

The Home controller contains two methods named Create(). The first Create() method has no parameters. This overload of the Create() method is used to display the HTML form for creating a new movie database record.

The second Create() method has a FormCollection parameter. This overload of the Create() method is called when the HTML form for creating a new movie is posted to the server. Notice that this second Create() method has an AcceptVerbs attribute that prevents the method from being called unless an HTTP Post operation is performed.

This second Create() method has been modified in the updated HomeController class in Listing 4. The new version of the Create() method accepts a Movie parameter and contains the logic for inserting a new movie into the Movies database table.

NOTE

Notice the Bind attribute. Because we don't want to update the Movie Id property from HTML form, we need to explicitly exclude this property.

Listing 4 – Controllers\HomeController.vb (modified Create method)

```
Function Create() As ActionResult

            Return View()

        End Function

        <AcceptVerbs(HttpVerbs.Post)> _

        Function Create(<_bind28_exclude3a_3d_22_id22_29_> ByVal movieToCreate As Movie) As ActionResult

            If Not ModelState.IsValid Then

                Return View()

            End If

            _db.AddToMovieSet(movieToCreate)

            _db.SaveChanges()

            Return RedirectToAction("Index")

        End Function
<!--_bind28_exclude3a_3d_22_id22_29_-->
```

Visual Studio makes it easy to create the form for creating a new movie database record (see Figure 12). Follow these steps:

1. Right-click the Create() method in the code editor and select the menu option **Add View**.
2. Verify that the checkbox labeled **Create a strongly-typed view** is checked.
3. From the **View content** dropdown list, select the value *Create*.
4. From the **View data class** dropdown list, select the value *MovieApp.Movie*.
5. Click the **Add** button to create the new view.

Figure 12: Adding the Create view (Click to view full-size image)

Visual Studio generates the view in Listing 5 automatically. This view contains an HTML form that includes fields that correspond to each of the properties of the Movie class.

Listing 5 – Views\Home\Create.aspx

```
<%@ Page Title="" Language="VB" MasterPageFile="~/Views/Shared/Site.Master"
Inherits="System.Web.Mvc.ViewPage(Of MovieApp.Movie)" %>

    <asp:Content ID="Content3" ContentPlaceHolderID="TitleContent" runat="server">

       Create

    </asp:Content>

    <asp:Content ID="Content4" ContentPlaceHolderID="MainContent" runat="server">

        <h2>Create</h2>

        <%= Html.ValidationSummary("Create was unsuccessful. Please correct the errors and try again.") %>

        <% Using Html.BeginForm()%>

            <fieldset>

                <legend>Fields</legend>

                <p>

                    <label for="Id">Id:</label>

                    <%= Html.TextBox("Id") %>

                    <%= Html.ValidationMessage("Id", "*") %>

                </p>

                <p>

                    <label for="Title">Title:</label>

                    <%= Html.TextBox("Title") %>

                    <%= Html.ValidationMessage("Title", "*") %>

                </p>

                <p>

                    <label for="Director">Director:</label>

                    <%= Html.TextBox("Director") %>

                    <%= Html.ValidationMessage("Director", "*") %>

                </p>

                <p>

                    <label for="DateReleased">DateReleased:</label>

                    <%= Html.TextBox("DateReleased") %>

                    <%= Html.ValidationMessage("DateReleased", "*") %>

                </p>
```

```
            <p>
                <input type="submit" value="Create" />
            </p>
        </fieldset>
    <% End Using %>
    <div>
        <%=Html.ActionLink("Back to List", "Index") %>
    </div>
</asp:Content>
```

NOTE

The HTML form generated by the Add View dialog generates an Id form field. Because the Id column is an Identity column, we don't need this form field and you can safely remove it.

After you add the Create view, you can add new Movie records to the database. Run your application by pressing the F5 key and click the Create New link to see the form in Figure 13. If you complete and submit the form, a new movie database record is created.

Notice that you get form validation automatically. If you neglect to enter a release date for a movie, or you enter an invalid release date, then the form is redisplayed and the release date field is highlighted.

Figure 13: Creating a new movie database record (Click to view full-size image)

Editing Existing Database Records

In the previous sections, we discussed how you can list and create new database records. In this final section, we discuss how you can edit existing database records.

First, we need to generate the Edit form. This step is easy since Visual Studio will generate the Edit form for us automatically. Open the HomeController.vb class in the Visual Studio code editor and follow these steps:

1. Right-click the Edit() method in the code editor and select the menu option **Add View** (see Figure 14).
2. Check the checkbox labeled **Create a strongly-typed view**.
3. From the **View content** dropdown list, select the value *Edit*.
4. From the **View data class** dropdown list, select the value *MovieApp.Movie*.
5. Click the **Add** button to create the new view.

Completing these steps adds a new view named Edit.aspx to the Views\Home folder. This view contains an HTML form for editing a movie record.

Figure 14: Adding the Edit view (Click to view full-size image)

> **NOTE**
> The Edit view contains an HTML form field that corresponds to the Movie Id property. Because you don't want people editing the value of the Id property, you should remove this form field.

Finally, we need to modify the Home controller so that it supports editing a database record. The updated HomeController class is contained in Listing 6.

Listing 6 – Controllers\HomeController.vb (Edit methods)

```
Function Edit(ByVal id As Integer) As ActionResult

            Dim movieToEdit = (From m In _db.MovieSet _

                           Where m.Id = id _

                           Select m).First()

            Return View(movieToEdit)

        End Function

        <AcceptVerbs(HttpVerbs.Post)> _

        Function Edit(ByVal movieToEdit As Movie) As ActionResult

            Dim originalMovie = (From m In _db.MovieSet _

                       Where m.Id = movieToEdit.Id _

                       Select m).First()

            If Not ModelState.IsValid Then

                Return View(originalMovie)

            End If

            _db.ApplyPropertyChanges(originalMovie.EntityKey.EntitySetName, movieToEdit)

            _db.SaveChanges()

            Return RedirectToAction("Index")

        End Function
```

In Listing 6, I've added additional logic to both overloads of the Edit() method. The first Edit() method returns the movie database record that corresponds to the Id parameter passed to the method. The second overload performs the updates to a movie record in the database.

Notice that you must retrieve the original movie, and then call ApplyPropertyChanges(), to update the existing movie in the database.

Summary

The purpose of this tutorial was to give you a sense of the experience of building an ASP.NET MVC application. I hope that you discovered that building an ASP.NET MVC web application is very similar to the experience of building an Active Server Pages or ASP.NET application.

In this tutorial, we examined only the most basic features of the ASP.NET MVC framework. In future tutorials, we dive deeper into topics such as controllers, controller actions, views, view data, and HTML helpers.

How Do I: Return JSON Formatted Data for an AJAX Call in an ASP.NET MVC Web Application?

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels shows how to use the JsonResult and Json classes to return instances of classes as JSON formatted data. First, a sample MVC web application is created and a controller and associated view are added for customer information. Then a simple customer class is created as part of the data model. A GetCustomer() function is then added to the customer controller to retrieve data for a single customer in JSON format. Finally, script is added to the customer view that uses jQuery to make an AJAX call to GetCustomer() to retrieve the customer data in JSON format

How Do I: Work with Data in ASP.NET MVC Partial Views?

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels shows how to organize and pass data to partial views in an MVC application. A sample MVC application is created that contains domain models for several business entities as well as a view model that packages instances of the classes. A demo view is then created along with several partial views, all of which are strongly typed and make use of the view model class. The partial views are then added to the demo view and the instance of the view model is used to easily pass the appropriate data down to the partial views. Finally, the uses of the concepts implemented in the sample in a more extensive MVC application are discussed.

How Do I: Implement View Models to Manage Data for ASP.NET MVC Views?

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels shows how to use the concept of a "View Model" for managing data for ASP.NET MVC views. First, a sample MVC project is created that uses a ViewDataDictionary to package and pass data from a controller to a view. Next, a class is created which represents a view model for a view in the sample MVC project. As part of this implementation, the advantages of the view model approach are discussed. Finally, there is a discussion of how to partition the application logic when using a view model implementation.

How Do I: Create a Custom HTML Helper for an MVC Application?

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels shows how to create a custom HtmlHelper that is not available in the standard set in an MVC application. First, a sample MVC application is created with a demo controller and view to test the custom HtmlHelper. Next, a module is created with a public function that is an extension method which represents the implementation of the custom HtmlHelper. The custom helper is for creating `<img>` tags in a page and receives several inbound parameters including the id, url, and alt text for the image tag. The logic is then added to the function for returning the completed `<img>` tag with the specified information. Then the custom HtmlHelper is used on the demo page to display an image. Finally, the custom HtmlHelper is expanded to include multiple constructor overrides which provide flexibility for more easily creating different `<img>` tags.

How Do I: Work with Model Binders in an MVC Application?

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels shows how to use model binders to bind form data to complex business objects in models in an MVC application. First, an MVC application is created along with a simple model for a Customer class along with a controller and view for editing the customer data. Then, the automatic model binding of MVC is demonstrated with the customer class. Next, the Bind attribute is discussed and demonstrated as a mechanism for controlling the details of the binding process to include and exclude specific properties of a complex object. Finally, the use of namespace prefixes for segmenting form data on a page is discussed.

How Do I: Use HttpVerbs Attributes in an MVC Application?

2/20/2020 • 2 minutes to read • Edit Online

by Chris Pels

In this video Chris Pels shows how to use the HttpVerbs attributes to control access to MVC actions. First, a sample application is created with a default controller and view for editing the information. Next, a second Index action is added to the controller which has an HttpPost attribute which restricts it to being called only when an HTTP POST is used. As a follow-up, the AcceptVerbs() attribute is implemented as an alternative syntax for Visual Studio 2008. A use of the HttpVerbs for preventing the security risk associated with using an HTTP GET to perform a delete from a link is then discussed.

ASP.NET MVC 3 Overview

ASP.NET MVC 3 builds on ASP.NET MVC 1 and 2, adding great features that both simplify your code and allow deeper extensibility. This topic provides an overview of many of the new features that are included in this release, organized into the following sections:

- Extensible Scaffolding with MvcScaffold integration
- HTML 5 enabled project templates
- The Razor View Engine
- Support for Multiple View Engines

- Controller Improvements
- JavaScript and Ajax
- Model Validation Improvements
- Dependency Injection Improvements
- Other New Features

Extensible Scaffolding with MvcScaffold integration

The new Scaffolding system makes it easier to pick up and start using productively if you're entirely new to the framework, and to automate common development tasks if you're experienced and already know what you're doing.

This is supported by new NuGet *scaffolding* package called **MvcScaffolding**. The term "Scaffolding" is used by many software technologies to mean "quickly generating a basic outline of your software that you can then edit and customize". The scaffolding package we're creating for ASP.NET MVC is greatly beneficial in several scenarios:

- **If you're learning ASP.NET MVC for the first time**, because it gives you a fast way to get some useful, working code, that you can then edit and adapt according to your needs. It saves you from the trauma of looking at a blank page and having no idea where to start!
- **If you know ASP.NET MVC well and are now exploring some new add-on technology** such as an object-relational mapper, a view engine, a testing library, etc., because the creator of that technology may have also created a scaffolding package for it.
- **If your work involves repeatedly creating similar classes or files of some sort**, because you can create custom scaffolders that output test fixtures, deployment scripts, or whatever else you need. Everyone on your team can use your custom scaffolders, too.

Other features in MvcScaffolding include:

- Support for C# and VB projects
- Support for the Razor and ASPX view engines
- Supports scaffolding into ASP.NET MVC areas and using custom view layouts/masters
- You can easily customize the output by editing T4 templates
- You can add entirely new scaffolders using custom PowerShell logic and custom T4 templates. These (and any custom parameters you've given them) automatically appear in the console tab-completion list.
- You can get NuGet packages containing additional scaffolders for different technologies (e.g., there's a proof-of-concept one for LINQ to SQL now) and mix and match them together

The ASP.NET MVC 3 Tools Update includes great Visual Studio support for this scaffolding system, such as:

- Add Controller Dialog now supports full automatic scaffolding of Create, Read, Update, and Delete controller actions and corresponding views. By default, this scaffolds data access code using EF Code First.
- Add Controller Dialog supports *extensible scaffolds* via NuGet packages such as *MvcScaffolding*. This allows plugging in custom scaffolds into the dialog which would allow you to create scaffolds for other data access technologies such as NHibernate or even JET with ODBCDirect if you're so inclined!

For more information about Scaffolding in ASP.NET MVC 3, see the following resources:

- Steve Sanderson's post series, including:
  1. Introduction: Scaffold your ASP.NET MVC 3 project with the MvcScaffolding package
  2. Standard usage: Typical use cases and options
  3. One-to-Many Relationships
  4. Scaffolding Actions and Unit Tests
  5. Overriding the T4 templates

6. This post: Creating custom scaffolders

- Scott Hanselman's post from his PDC 2010 session Building a Blog with Microsoft "Unnamed Package of Web Love"
- MVC 3 Release Notes

HTML 5 Project Templates

The New Project dialog includes a checkbox enable HTML 5 versions of project templates. These templates leverage Modernizr 1.7 to provide compatibility support for HTML 5 and CSS 3 in down-level browsers.

The Razor View Engine

ASP.NET MVC 3 comes with a new view engine named Razor that offers the following benefits:

- Razor syntax is clean and concise, requiring a minimum number of keystrokes.
- Razor is easy to learn, in part because it's based on existing languages like C# and Visual Basic.
- Visual Studio includes IntelliSense and code colorization for Razor syntax.
- Razor views can be unit tested without requiring that you run the application or launch a web server.

Some new Razor features include the following:

- `@model` syntax for specifying the type being passed to the view.
- `@* *@` comment syntax.
- The ability to specify defaults (such as `layoutpage`) once for an entire site.
- The `Html.Raw` method for displaying text without HTML-encoding it.
- Support for sharing code among multiple views (*_viewstart.cshtml* or *_viewstart.vbhtml* files).

Razor also includes new HTML helpers, such as the following:

- `Chart`. Renders a chart, offering the same features as the chart control in ASP.NET 4.
- `WebGrid`. Renders a data grid, complete with paging and sorting functionality.
- `Crypto`. Uses hashing algorithms to create properly salted and hashed passwords.
- `WebImage`. Renders an image.
- `WebMail`. Sends an email message.

For more information about Razor, see the following resources:

- Scott Guthrie's blog post introducing Razor
- Scott Guthrie's blog post introducing the @model keyword
- Scott Guthrie's blog post introducing Razor layouts
- Razor API Quick Reference
- MVC 3 Release Notes

Support for Multiple View Engines

The **Add View** dialog box in ASP.NET MVC 3 lets you choose the view engine you want to work with, and the **New Project** dialog box lets you specify the default view engine for a project. You can choose the Web Forms view engine (ASPX), Razor, or an open-source view engine such as Spark, NHaml, or NDjango.

Controller Improvements

Global Action Filters

Sometimes you want to perform logic either before an action method runs or after an action method runs. To support this, ASP.NET MVC 2 provided action filters. Action filters are custom attributes that provide a declarative means to add pre-action and post-action behavior to specific controller action methods. However, in some cases you might want to specify pre-action or post-action behavior that applies to all action methods. MVC 3 lets you specify global filters by adding them to the `GlobalFilters` collection. For more information about global action filters, see the following resources:

- Scott Guthrie's blog on the MVC 3 Preview
- Filtering in ASP.NET MVC

New "ViewBag" Property

MVC 2 controllers support a `ViewData` property that enables you to pass data to a view template using a late-bound dictionary API. In MVC 3, you can also use somewhat simpler syntax with the `ViewBag` property to accomplish the same purpose. For example, instead of writing `ViewData["Message"]="text"`, you can write `ViewBag.Message="text"`. You do not need to define any strongly-typed classes to use the `ViewBag` property. Because it is a dynamic property, you can instead just get or set properties and it will resolve them dynamically at run time. Internally, `ViewBag` properties are stored as name/value pairs in the `ViewData` dictionary. (Note: in most pre-release versions of MVC 3, the `ViewBag` property was named the `ViewModel` property.)

New "ActionResult" Types

The following `ActionResult` types and corresponding helper methods are new or enhanced in MVC 3:

- HttpNotFoundResult. Returns a 404 HTTP status code to the client.
- RedirectResult. Returns a temporary redirect (HTTP 302 status code) or a permanent redirect (HTTP 301 status code), depending on a Boolean parameter. In conjunction with this change, the Controller class now has three methods for performing permanent redirects: `RedirectPermanent`, `RedirectToRoutePermanent`, and `RedirectToActionPermanent`. These methods return an instance of `RedirectResult` with the `Permanent` property set to `true`.
- HttpStatusCodeResult. Returns a user-specified HTTP status code.

JavaScript and Ajax Improvements

By default, Ajax and validation helpers in MVC 3 use an unobtrusive JavaScript approach. Unobtrusive JavaScript avoids injecting inline JavaScript into HTML. This makes your HTML smaller and less cluttered, and makes it easier to swap out or customize JavaScript libraries. Validation helpers in MVC 3 also use the `jQueryValidate` plugin by default. If you want MVC 2 behavior, you can disable unobtrusive JavaScript using a *web.config* file setting. For more information about JavaScript and Ajax improvements, see the following resources:

- Basic introduction to unobtrusive JavaScript on the Wikipedia site
- Brad Wilson's Unobtrusive JavaScript Post
- Brad Wilson's Unobtrusive JavaScript Validation Post
- Creating a MVC 3 Application with Razor and Unobtrusive JavaScript (tutorial on the ASP.NET site)
- MVC 3 Release Notes

Client-Side Validation Enabled by Default

In earlier versions of MVC, you need to explicitly call the `Html.EnableClientValidation` method from a view in order to enable client-side validation. In MVC 3 this is no longer required because client-side validation is enabled by default. (You can disable this using a setting in the *web.config* file.)

In order for client-side validation to work, you still need to reference the appropriate jQuery and jQuery Validation libraries in your site. You can host those libraries on your own server or reference them from a content delivery network (CDN) like the CDNs from Microsoft or Google.

Remote Validator

ASP.NET MVC 3 supports the new RemoteAttribute class that enables you to take advantage of the jQuery Validation plug-in's remote validator support. This enables the client-side validation library to automatically call a custom method that you define on the server in order to perform validation logic that can only be done server-side.

In the following example, the `Remote` attribute specifies that client validation will call an action named `UserNameAvailable` on the `UsersController` class in order to validate the `UserName` field.

```
public class User
{
    [Remote("UserNameAvailable", "Users")]
    public string UserName { get; set; }
}
```

The following example shows the corresponding controller.

```
public class UsersController
{
    public bool UserNameAvailable(string username)
    {
        if(MyRepository.UserNameExists(username))
        {
            return "false";
        }
        return "true";
    }
}
```

For more information about how to use the `Remote` attribute, see How to: Implement Remote Validation in ASP.NET MVC in the MSDN library.

JSON Binding Support

ASP.NET MVC 3 includes built-in JSON binding support that enables action methods to receive JSON-encoded data and model-bind it to action-method parameters. This capability is useful in scenarios involving client templates and data binding. (Client templates enable you to format and display a single data item or set of data items by using templates that execute on the client.) MVC 3 enables you to easily connect client templates with action methods on the server that send and receive JSON data. For more information about JSON binding support, see the **JavaScript and AJAX Improvements** section of Scott Guthrie's MVC 3 Preview blog post.

Model Validation Improvements

"DataAnnotations" Metadata Attributes

ASP.NET MVC 3 supports `DataAnnotations` metadata attributes such as `DisplayAttribute`.

"ValidationAttribute" Class

The `ValidationAttribute` class was improved in the .NET Framework 4 to support a new `IsValid` overload that provides more information about the current validation context, such as what object is being validated. This enables richer scenarios where you can validate the current value based on another property of the model. For example, the new `CompareAttribute` attribute lets you compare the values of two properties of a model. In the following example, the `ComparePassword` property must match the `Password` field in order to be valid.

```
public class User
{
    [Required]
    public string Password { get; set; }
    [Required, Compare("Password")]
    public string ComparePassword { get; set; }
}
```

Validation Interfaces

The IValidatableObject interface enables you to perform model-level validation, and it enables you to provide validation error messages that are specific to the state of the overall model, or between two properties within the model. MVC 3 now retrieves errors from the `IValidatableObject` interface when model binding, and automatically flags or highlights affected fields within a view using the built-in HTML form helpers.

The IClientValidatable interface enables ASP.NET MVC to discover at run time whether a validator has support for client validation. This interface has been designed so that it can be integrated with a variety of validation frameworks.

For more information about validation interfaces, see the **Model Validation Improvements** section of Scott Guthrie's MVC 3 Preview blog post. (However, note that the reference to "IValidateObject" in the blog should be "IValidatableObject".)

Dependency Injection Improvements

ASP.NET MVC 3 provides better support for applying Dependency Injection (DI) and for integrating with Dependency Injection or Inversion of Control (IOC) containers. Support for DI has been added in the following areas:

- Controllers (registering and injecting controller factories, injecting controllers).
- Views (registering and injecting view engines, injecting dependencies into view pages).
- Action filters (locating and injecting filters).
- Model binders (registering and injecting).
- Model validation providers (registering and injecting).
- Model metadata providers (registering and injecting).
- Value providers (registering and injecting).

MVC 3 supports the Common Service Locator library and any DI container that supports that library's `IServiceLocator` interface. It also supports a new `IDependencyResolver` interface that makes it easier to integrate DI frameworks.

For more information about DI in MVC 3, see the following resources:

- Brad Wilson's series of blog posts on Service Location
- MVC 3 Release Notes

Other New Features

NuGet Integration

ASP.NET MVC 3 automatically installs and enables NuGet as part of its setup. NuGet is a free open-source package manager that makes it easy to find, install, and use .NET libraries and tools in your projects. It works with all Visual Studio project types (including ASP.NET Web Forms and ASP.NET MVC).

NuGet enables developers who maintain open source projects (for example, projects like Moq, NHibernate, Ninject, StructureMap, NUnit, Windsor, RhinoMocks, and Elmah) to package their libraries and register them in an online

gallery. It is then easy for .NET developers who want to use one of these libraries to find the package and install it in projects they are working on.

With the ASP.NET 3 Tools Update, project templates include JavaScript libraries pre-installed NuGet packages, so they are updatable via NuGet. Entity Framework Code First is also pre-installed as a NuGet package.

For more information about NuGet, see the NuGet documentation.

Partial-Page Output Caching

ASP.NET MVC has supported output caching of full page responses since version 1. MVC 3 also supports partial-page output caching, which allows you to easily cache regions or fragments of a response. For more information about caching, see the **Partial Page Output Caching** section of Scott Guthrie's blog post on the MVC 3 release candidate and the **Child Action Output Caching** section of the MVC 3 Release Notes.

Granular Control over Request Validation

ASP.NET MVC has built-in request validation that automatically helps protect against XSS and HTML injection attacks. However, sometimes you want to explicitly disable request validation, such as if you want to let users post HTML content (for example, in blog entries or CMS content). You can now add an AllowHtml attribute to models or view models to disable request validation on a per-property basis during model binding. For more information about request validation, see the following resources:

- The **Unobtrusive JavaScript and Validation** section in Scott Guthrie's blog post on the MVC 3 release candidate.
- MVC 3 Release Notes

Extensible "New Project" Dialog Box

In ASP.NET MVC 3 you can add project templates, view engines, and unit test project frameworks to the **New Project** dialog box.

Template Scaffolding Improvements

ASP.NET MVC 3 scaffolding templates do a better job of identifying primary-key properties on models and handling them appropriately than in earlier versions of MVC. (For example, the scaffolding templates now make sure that the primary key is not scaffolded as an editable form field.)

By default, the Create and Edit scaffolds now use the `Html.EditorFor` helper instead of the `Html.TextBoxFor` helper. This improves support for metadata on the model in the form of data annotation attributes when the **Add View** dialog box generates a view.

New Overloads for "Html.LabelFor" and "Html.LabelForModel"

New method overloads have been added for the `LabelFor` and `LabelForModel` helper methods. The new overloads enable you to specify or override the label text.

Sessionless Controller Support

In ASP.NET MVC 3 you can indicate whether you want a controller class to use session state, and if so, whether session state should be read/write or read-only. For more information about sessionless controller support, see MVC 3 Release Notes.

New "AdditionalMetadataAttribute" Class

You can use the AdditionalMetadata attribute to populate the `ModelMetadata.AdditionalValues` dictionary for a model property. For example, if a view model has a property that should be displayed only to an administrator, you can annotate that property as shown in the following example:

```
public class ProductViewModel
{
    [AdditionalMetadata("AdminOnly", true)]
    public string RefundCode {get; set;}
}
```

This metadata is made available to any display or editor template when a product view model is rendered. It is up to you to interpret the metadata information.

AccountController improvements

The AccountController in the Internet project template has been greatly improved.

New Intranet Project Template

A new Intranet Project Template is included which enables Windows Authentication and removes the AccountController.

Get Started with ASP.NET Web API 2 (C#)

3/11/2020 • 8 minutes to read • Edit Online

by Mike Wasson

Download Completed Project

In this tutorial, you will use ASP.NET Web API to create a web API that returns a list of products.

HTTP is not just for serving up web pages. HTTP is also a powerful platform for building APIs that expose services and data. HTTP is simple, flexible, and ubiquitous. Almost any platform that you can think of has an HTTP library, so HTTP services can reach a broad range of clients, including browsers, mobile devices, and traditional desktop applications.

ASP.NET Web API is a framework for building web APIs on top of the .NET Framework.

Software versions used in the tutorial

- Visual Studio 2017
- Web API 2

See Create a web API with ASP.NET Core and Visual Studio for Windows for a newer version of this tutorial.

Create a Web API Project

In this tutorial, you will use ASP.NET Web API to create a web API that returns a list of products. The front-end web page uses jQuery to display the results.

Start Visual Studio and select **New Project** from the **Start** page. Or, from the **File** menu, select **New** and then **Project**.

In the **Templates** pane, select **Installed Templates** and expand the **Visual C#** node. Under **Visual C#**, select **Web**. In the list of project templates, select **ASP.NET Web Application**. Name the project "ProductsApp" and click **OK**.

In the **New ASP.NET Project** dialog, select the **Empty** template. Under "Add folders and core references for", check **Web API**. Click **OK**.

NOTE

You can also create a Web API project using the "Web API" template. The Web API template uses ASP.NET MVC to provide API help pages. I'm using the Empty template for this tutorial because I want to show Web API without MVC. In general, you don't need to know ASP.NET MVC to use Web API.

Adding a Model

A *model* is an object that represents the data in your application. ASP.NET Web API can automatically serialize your model to JSON, XML, or some other format, and then write the serialized data into the body of the HTTP response message. As long as a client can read the serialization format, it can deserialize the object. Most clients can parse either XML or JSON. Moreover, the client can indicate which format it wants by setting the Accept header in the HTTP request message.

Let's start by creating a simple model that represents a product.

If Solution Explorer is not already visible, click the **View** menu and select **Solution Explorer**. In Solution Explorer, right-click the Models folder. From the context menu, select **Add** then select **Class**.

Name the class "Product". Add the following properties to the `Product` class.

```
namespace ProductsApp.Models
{
    public class Product
    {
        public int Id { get; set; }
        public string Name { get; set; }
        public string Category { get; set; }
        public decimal Price { get; set; }
    }
}
```

Adding a Controller

In Web API, a *controller* is an object that handles HTTP requests. We'll add a controller that can return either a list of products or a single product specified by ID.

> **NOTE**
>
> If you have used ASP.NET MVC, you are already familiar with controllers. Web API controllers are similar to MVC controllers, but inherit the **ApiController** class instead of the **Controller** class.

In **Solution Explorer**, right-click the Controllers folder. Select **Add** and then select **Controller**.

In the **Add Scaffold** dialog, select **Web API Controller - Empty**. Click **Add**.

In the **Add Controller** dialog, name the controller "ProductsController". Click **Add**.

The scaffolding creates a file named ProductsController.cs in the Controllers folder.

> **NOTE**
>
> You don't need to put your controllers into a folder named Controllers. The folder name is just a convenient way to organize your source files.

If this file is not open already, double-click the file to open it. Replace the code in this file with the following:

```
using ProductsApp.Models;
using System;
using System.Collections.Generic;
using System.Linq;
using System.Net;
using System.Web.Http;

namespace ProductsApp.Controllers
{
    public class ProductsController : ApiController
    {
        Product[] products = new Product[]
        {
            new Product { Id = 1, Name = "Tomato Soup", Category = "Groceries", Price = 1 },
            new Product { Id = 2, Name = "Yo-yo", Category = "Toys", Price = 3.75M },
            new Product { Id = 3, Name = "Hammer", Category = "Hardware", Price = 16.99M }
        };

        public IEnumerable<Product> GetAllProducts()
        {
            return products;
        }

        public IHttpActionResult GetProduct(int id)
        {
            var product = products.FirstOrDefault((p) => p.Id == id);
            if (product == null)
            {
                return NotFound();
            }
            return Ok(product);
        }
    }
}
```

To keep the example simple, products are stored in a fixed array inside the controller class. Of course, in a real application, you would query a database or use some other external data source.

The controller defines two methods that return products:

- The `GetAllProducts` method returns the entire list of products as an **IEnumerable<Product>** type.
- The `GetProduct` method looks up a single product by its ID.

That's it! You have a working web API. Each method on the controller corresponds to one or more URIs:

CONTROLLER METHOD	URI
GetAllProducts	/api/products
GetProduct	/api/products/*id*

For the `GetProduct` method, the *id* in the URI is a placeholder. For example, to get the product with ID of 5, the URI is `api/products/5`.

For more information about how Web API routes HTTP requests to controller methods, see Routing in ASP.NET Web API.

Calling the Web API with Javascript and jQuery

In this section, we'll add an HTML page that uses AJAX to call the web API. We'll use jQuery to make the AJAX calls and also to update the page with the results.

In Solution Explorer, right-click the project and select **Add**, then select **New Item**.

In the **Add New Item** dialog, select the **Web** node under **Visual C#**, and then select the **HTML Page** item. Name the page "index.html".

Replace everything in this file with the following:

```
<!DOCTYPE html>
<html xmlns="http://www.w3.org/1999/xhtml">
<head>
  <title>Product App</title>
</head>
<body>

  <div>
    <h2>All Products</h2>
    <ul id="products" />
  </div>
  <div>
    <h2>Search by ID</h2>
    <input type="text" id="prodId" size="5" />
    <input type="button" value="Search" onclick="find();" />
    <p id="product" />
  </div>

  <script src="https://ajax.aspnetcdn.com/ajax/jQuery/jquery-2.0.3.min.js"></script>
  <script>
    var uri = 'api/products';

    $(document).ready(function () {
      // Send an AJAX request
      $.getJSON(uri)
          .done(function (data) {
            // On success, 'data' contains a list of products.
            $.each(data, function (key, item) {
              // Add a list item for the product.
              $('<li>', { text: formatItem(item) }).appendTo($('#products'));
            });
          });
    });

    function formatItem(item) {
      return item.Name + ': $' + item.Price;
    }

    function find() {
      var id = $('#prodId').val();
      $.getJSON(uri + '/' + id)
          .done(function (data) {
            $('#product').text(formatItem(data));
          })
          .fail(function (jqXHR, textStatus, err) {
            $('#product').text('Error: ' + err);
          });
    }
  </script>
</body>
</html>
```

There are several ways to get jQuery. In this example, I used the Microsoft Ajax CDN. You can also download it from http://jquery.com/, and the ASP.NET "Web API" project template includes jQuery as well.

Getting a List of Products

To get a list of products, send an HTTP GET request to "/api/products".

The jQuery getJSON function sends an AJAX request. The response contains array of JSON objects. The `done` function specifies a callback that is called if the request succeeds. In the callback, we update the DOM with the product information.

```
$(document).ready(function () {
    // Send an AJAX request
    $.getJSON(apiUrl)
        .done(function (data) {
            // On success, 'data' contains a list of products.
            $.each(data, function (key, item) {
                // Add a list item for the product.
                $('<li>', { text: formatItem(item) }).appendTo($('#products'));
            });
        });
});
```

Getting a Product By ID

To get a product by ID, send an HTTP GET request to "/api/products/*id*", where *id* is the product ID.

```
function find() {
    var id = $('#prodId').val();
    $.getJSON(apiUrl + '/' + id)
        .done(function (data) {
            $('#product').text(formatItem(data));
        })
        .fail(function (jqXHR, textStatus, err) {
            $('#product').text('Error: ' + err);
        });
}
```

We still call `getJSON` to send the AJAX request, but this time we put the ID in the request URI. The response from this request is a JSON representation of a single product.

Running the Application

Press F5 to start debugging the application. The web page should look like the following:

To get a product by ID, enter the ID and click Search:

If you enter an invalid ID, the server returns an HTTP error:

Using F12 to View the HTTP Request and Response

When you are working with an HTTP service, it can be very useful to see the HTTP request and response messages. You can do this by using the F12 developer tools in Internet Explorer 9. From Internet Explorer 9, press **F12** to open the tools. Click the **Network** tab and press **Start Capturing**. Now go back to the web page and press **F5** to reload the web page. Internet Explorer will capture the HTTP traffic between the browser and the web server. The summary view shows all the network traffic for a page:

Locate the entry for the relative URI "api/products/". Select this entry and click **Go to detailed view**. In the detail view, there are tabs to view the request and response headers and bodies. For example, if you click the **Request headers** tab, you can see that the client requested "application/json" in the Accept header.

If you click the Response body tab, you can see how the product list was serialized to JSON. Other browsers have similar functionality. Another useful tool is Fiddler, a web debugging proxy. You can use Fiddler to view your HTTP traffic, and also to compose HTTP requests, which gives you full control over the HTTP headers in the request.

See this App Running on Azure

Would you like to see the finished site running as a live web app? You can deploy a complete version of the app to your Azure account by simply clicking the following button.

Deploy to Azure

You need an Azure account to deploy this solution to Azure. If you do not already have an account, you have the following options:

- Open an Azure account for free - You get credits you can use to try out paid Azure services, and even after they're used up you can keep the account and use free Azure services.
- Activate MSDN subscriber benefits - Your MSDN subscription gives you credits every month that you can use for paid Azure services.

Next Steps

- For a more complete example of an HTTP service that supports POST, PUT, and DELETE actions and writes to a database, see Using Web API 2 with Entity Framework 6.
- For more about creating fluid and responsive web applications on top of an HTTP service, see ASP.NET Single Page Application.
- For information about how to deploy a Visual Studio web project to Azure App Service, see Create an ASP.NET web app in Azure App Service.

Action Results in Web API 2

2/20/2020 • 4 minutes to read • Edit Online

Consider using ASP.NET Core web API. It has the following advantages over ASP.NET 4.x Web API:

- ASP.NET Core is an open-source, cross-platform framework for building modern, cloud-based web apps on Windows, macOS, and Linux.
- The ASP.NET Core MVC controllers and web API controllers are unified.
- Architected for testability.
- Ability to develop and run on Windows, macOS, and Linux.
- Open-source and community-focused.
- Integration of modern, client-side frameworks and development workflows.
- A cloud-ready, environment-based configuration system.
- Built-in dependency injection.
- A lightweight, high-performance, and modular HTTP request pipeline.
- Ability to host on Kestrel, IIS, HTTP.sys, Nginx, Apache, and Docker.
- Side-by-side versioning.
- Tooling that simplifies modern web development.

This topic describes how ASP.NET Web API converts the return value from a controller action into an HTTP response message.

A Web API controller action can return any of the following:

1. void
2. **HttpResponseMessage**
3. **IHttpActionResult**
4. Some other type

Depending on which of these is returned, Web API uses a different mechanism to create the HTTP response.

RETURN TYPE	HOW WEB API CREATES THE RESPONSE
void	Return empty 204 (No Content)
HttpResponseMessage	Convert directly to an HTTP response message.
IHttpActionResult	Call **ExecuteAsync** to create an **HttpResponseMessage**, then convert to an HTTP response message.
Other type	Write the serialized return value into the response body; return 200 (OK).

The rest of this topic describes each option in more detail.

void

If the return type is `void`, Web API simply returns an empty HTTP response with status code 204 (No Content).

Example controller:

```
public class ValuesController : ApiController
{
    public void Post()
    {
    }
}
```

HTTP response:

```
HTTP/1.1 204 No Content
Server: Microsoft-IIS/8.0
Date: Mon, 27 Jan 2014 02:13:26 GMT
```

HttpResponseMessage

If the action returns an HttpResponseMessage, Web API converts the return value directly into an HTTP response message, using the properties of the **HttpResponseMessage** object to populate the response.

This option gives you a lot of control over the response message. For example, the following controller action sets the Cache-Control header.

```
public class ValuesController : ApiController
{
    public HttpResponseMessage Get()
    {
        HttpResponseMessage response = Request.CreateResponse(HttpStatusCode.OK, "value");
        response.Content = new StringContent("hello", Encoding.Unicode);
        response.Headers.CacheControl = new CacheControlHeaderValue()
        {
            MaxAge = TimeSpan.FromMinutes(20)
        };
        return response;
    }
}
```

Response:

```
HTTP/1.1 200 OK
Cache-Control: max-age=1200
Content-Length: 10
Content-Type: text/plain; charset=utf-16
Server: Microsoft-IIS/8.0
Date: Mon, 27 Jan 2014 08:53:35 GMT

hello
```

If you pass a domain model to the **CreateResponse** method, Web API uses a media formatter to write the serialized model into the response body.

```
public HttpResponseMessage Get()
{
    // Get a list of products from a database.
    IEnumerable<Product> products = GetProductsFromDB();

    // Write the list to the response body.
    HttpResponseMessage response = Request.CreateResponse(HttpStatusCode.OK, products);
    return response;
}
```

Web API uses the Accept header in the request to choose the formatter. For more information, see Content Negotiation.

IHttpActionResult

The **IHttpActionResult** interface was introduced in Web API 2. Essentially, it defines an **HttpResponseMessage** factory. Here are some advantages of using the **IHttpActionResult** interface:

- Simplifies unit testing your controllers.
- Moves common logic for creating HTTP responses into separate classes.
- Makes the intent of the controller action clearer, by hiding the low-level details of constructing the response.

IHttpActionResult contains a single method, **ExecuteAsync**, which asynchronously creates an **HttpResponseMessage** instance.

```
public interface IHttpActionResult
{
    Task<HttpResponseMessage> ExecuteAsync(CancellationToken cancellationToken);
}
```

If a controller action returns an **IHttpActionResult**, Web API calls the **ExecuteAsync** method to create an **HttpResponseMessage**. Then it converts the **HttpResponseMessage** into an HTTP response message.

Here is a simple implementation of **IHttpActionResult** that creates a plain text response:

```
public class TextResult : IHttpActionResult
{
    string _value;
    HttpRequestMessage _request;

    public TextResult(string value, HttpRequestMessage request)
    {
        _value = value;
        _request = request;
    }
    public Task<HttpResponseMessage> ExecuteAsync(CancellationToken cancellationToken)
    {
        var response = new HttpResponseMessage()
        {
            Content = new StringContent(_value),
            RequestMessage = _request
        };
        return Task.FromResult(response);
    }
}
```

Example controller action:

```
public class ValuesController : ApiController
{
    public IHttpActionResult Get()
    {
        return new TextResult("hello", Request);
    }
}
```

Response:

```
HTTP/1.1 200 OK
Content-Length: 5
Content-Type: text/plain; charset=utf-8
Server: Microsoft-IIS/8.0
Date: Mon, 27 Jan 2014 08:53:35 GMT

hello
```

More often, you use the **IHttpActionResult** implementations defined in the **System.Web.Http.Results** namespace. The **ApiController** class defines helper methods that return these built-in action results.

In the following example, if the request does not match an existing product ID, the controller calls ApiController.NotFound to create a 404 (Not Found) response. Otherwise, the controller calls ApiController.OK, which creates a 200 (OK) response that contains the product.

```
public IHttpActionResult Get (int id)
{
    Product product = _repository.Get (id);
    if (product == null)
    {
        return NotFound(); // Returns a NotFoundResult
    }
    return Ok(product);  // Returns an OkNegotiatedContentResult
}
```

Other Return Types

For all other return types, Web API uses a media formatter to serialize the return value. Web API writes the serialized value into the response body. The response status code is 200 (OK).

```
public class ProductsController : ApiController
{
    public IEnumerable<Product> Get()
    {
        return GetAllProductsFromDB();
    }
}
```

A disadvantage of this approach is that you cannot directly return an error code, such as 404. However, you can throw an **HttpResponseException** for error codes. For more information, see Exception Handling in ASP.NET Web API.

Web API uses the Accept header in the request to choose the formatter. For more information, see Content Negotiation.

Example request

```
GET http://localhost/api/products HTTP/1.1
User-Agent: Fiddler
Host: localhost:24127
Accept: application/json
```

Example response

```
HTTP/1.1 200 OK
Content-Type: application/json; charset=utf-8
Server: Microsoft-IIS/8.0
Date: Mon, 27 Jan 2014 08:53:35 GMT
Content-Length: 56

[{"Id":1,"Name":"Yo-yo","Category":"Toys","Price":6.95}]
```

Using Web API with ASP.NET Web Forms

2/20/2020 • 3 minutes to read • Edit Online

by Mike Wasson

This tutorial walks you through the steps to add Web API to a traditional ASP.NET Web Forms application in ASP.NET 4.x.

Overview

Although ASP.NET Web API is packaged with ASP.NET MVC, it is easy to add Web API to a traditional ASP.NET Web Forms application.

To use Web API in a Web Forms application, there are two main steps:

- Add a Web API controller that derives from the **ApiController** class.
- Add a route table to the **Application_Start** method.

Create a Web Forms Project

Start Visual Studio and select **New Project** from the **Start** page. Or, from the **File** menu, select **New** and then **Project**.

In the **Templates** pane, select **Installed Templates** and expand the **Visual C#** node. Under **Visual C#**, select **Web**. In the list of project templates, select **ASP.NET Web Forms Application**. Enter a name for the project and click **OK**.

Create the Model and Controller

This tutorial uses the same model and controller classes as the Getting Started tutorial.

First, add a model class. In **Solution Explorer**, right-click the project and select **Add Class**. Name the class Product, and add the following implementation:

```
public class Product
{
    public int Id { get; set; }
    public string Name { get; set; }
    public decimal Price { get; set; }
    public string Category { get; set; }
}
```

Next, add a Web API controller to the project., A *controller* is the object that handles HTTP requests for Web API.

In **Solution Explorer**, right-click the project. Select **Add New Item**.

Under **Installed Templates**, expand **Visual C#** and select **Web**. Then, from the list of templates, select **Web API Controller Class**. Name the controller "ProductsController" and click **Add**.

The **Add New Item** wizard will create a file named ProductsController.cs. Delete the methods that the wizard

included and add the following methods:

```
namespace WebForms
{
    using System;
    using System.Collections.Generic;
    using System.Linq;
    using System.Net;
    using System.Net.Http;
    using System.Web.Http;

    public class ProductsController : ApiController
    {

        Product[] products = new Product[]
        {
            new Product { Id = 1, Name = "Tomato Soup", Category = "Groceries", Price = 1 },
            new Product { Id = 2, Name = "Yo-yo", Category = "Toys", Price = 3.75M },
            new Product { Id = 3, Name = "Hammer", Category = "Hardware", Price = 16.99M }
        };

        public IEnumerable<Product> GetAllProducts()
        {
            return products;
        }

        public Product GetProductById(int id)
        {
            var product = products.FirstOrDefault((p) => p.Id == id);
            if (product == null)
            {
                throw new HttpResponseException(HttpStatusCode.NotFound);
            }
            return product;
        }

        public IEnumerable<Product> GetProductsByCategory(string category)
        {
            return products.Where(
                (p) => string.Equals(p.Category, category,
                    StringComparison.OrdinalIgnoreCase));
        }
    }
}
```

For more information about the code in this controller, see the Getting Started tutorial.

Add Routing Information

Next, we'll add a URI route so that URIs of the form "/api/products/" are routed to the controller.

In **Solution Explorer**, double-click Global.asax to open the code-behind file Global.asax.cs. Add the following **using** statement.

```
using System.Web.Http;
```

Then add the following code to the **Application_Start** method:

```
RouteTable.Routes.MapHttpRoute(
    name: "DefaultApi",
    routeTemplate: "api/{controller}/{id}",
    defaults: new { id = System.Web.Http.RouteParameter.Optional }
);
```

For more information about routing tables, see Routing in ASP.NET Web API.

Add Client-Side AJAX

That's all you need to create a web API that clients can access. Now let's add an HTML page that uses jQuery to call the API.

Make sure your master page (for example, *Site.Master*) includes a `ContentPlaceHolder` with `ID="HeadContent"`:

```
<asp:ContentPlaceHolder runat="server" ID="HeadContent"></asp:ContentPlaceHolder>
```

Open the file Default.aspx. Replace the boilerplate text that is in the main content section, as shown:

```
<%@ Page Title="Home Page" Language="C#" MasterPageFile="~/Site.Master"
    AutoEventWireup="true" CodeBehind="Default.aspx.cs" Inherits="WebForms._Default" %>

<asp:Content ID="HeaderContent" runat="server" ContentPlaceHolderID="HeadContent">
</asp:Content>

<asp:Content ID="BodyContent" runat="server" ContentPlaceHolderID="MainContent">
    <h2>Products</h2>
    <table>
    <thead>
        <tr><th>Name</th><th>Price</th></tr>
    </thead>
    <tbody id="products">
    </tbody>
    </table>
</asp:Content>
```

Next, add a reference to the jQuery source file in the `HeaderContent` section:

```
<asp:Content ID="HeaderContent" runat="server" ContentPlaceHolderID="HeadContent">
    <script src="Scripts/jquery-1.10.2.min.js" type="text/javascript"></script>
</asp:Content>
```

Note: You can easily add the script reference by dragging and dropping the file from **Solution Explorer** into the code editor window.

Below the jQuery script tag, add the following script block:

```
<script type="text/javascript">
    function getProducts() {
        $.getJSON("api/products",
            function (data) {
                $('#products').empty(); // Clear the table body.

                // Loop through the list of products.
                $.each(data, function (key, val) {
                    // Add a table row for the product.
                    var row = '<td>' + val.Name + '</td><td>' + val.Price + '</td>';
                    $('<tr/>', { html: row })  // Append the name.
                        .appendTo($('#products'));
                });
            });
        }

        $(document).ready(getProducts);
</script>
```

When the document loads, this script makes an AJAX request to "api/products". The request returns a list of products in JSON format. The script adds the product information to the HTML table.

When you run the application, it should look like this:

Creating Help Pages for ASP.NET Web API

2/20/2020 • 5 minutes to read • Edit Online

by Mike Wasson

This tutorial with code shows how to create help pages for ASP.NET Web API in ASP.NET 4.x.

When you create a web API, it is often useful to create a help page, so that other developers will know how to call your API. You could create all of the documentation manually, but it is better to autogenerate as much as possible. To make this task easier, ASP.NET Web API provides a library for auto-generating help pages at run time.

Creating API Help Pages

Install ASP.NET and Web Tools 2012.2 Update. This update integrates help pages into the Web API project template.

Next, create a new ASP.NET MVC 4 project and select the Web API project template. The project template creates an example API controller named `ValuesController`. The template also creates the API help pages. All of the code files for the help page are placed in the Areas folder of the project.

When you run the application, the home page contains a link to the API help page. From the home page, the

relative path is /Help.

This link brings you to an API summary page.

The MVC view for this page is defined in Areas/HelpPage/Views/Help/Index.cshtml. You can edit this page to modify the layout, introduction, title, styles, and so forth.

The main part of the page is a table of APIs, grouped by controller. The table entries are generated dynamically, using the **IApiExplorer** interface. (I'll talk more about this interface later.) If you add a new API controller, the table is automatically updated at run time.

The "API" column lists the HTTP method and relative URI. The "Description" column contains documentation for each API. Initially, the documentation is just placeholder text. In the next section, I'll show you how to add documentation from XML comments.

Each API has a link to a page with more detailed information, including example request and response bodies.

Adding Help Pages to an Existing Project

You can add help pages to an existing Web API project by using NuGet Package Manager. This option is useful you start from a different project template than the "Web API" template.

From the **Tools** menu, select **NuGet Package Manager**, and then select **Package Manager Console**. In the Package Manager Console window, type one of the following commands:

For a **C#** application: `Install-Package Microsoft.AspNet.WebApi.HelpPage`

For a **Visual Basic** application: `Install-Package Microsoft.AspNet.WebApi.HelpPage.VB`

There are two packages, one for C# and one for Visual Basic. Make sure to use the one that matches your project.

This command installs the necessary assemblies and adds the MVC views for the help pages (located in the Areas/HelpPage folder). You'll need to manually add a link to the Help page. The URI is /Help. To create a link in a razor view, add the following:

```
@Html.ActionLink("API", "Index", "Help", new { area = "" }, null)
```

Also, make sure to register areas. In the Global.asax file, add the following code to the **Application_Start** method, if it is not there already:

```
protected void Application_Start()
{
    // Add this code, if not present.
    AreaRegistration.RegisterAllAreas();

    // ...
}
```

Adding API Documentation

By default, the help pages have placeholder strings for documentation. You can use XML documentation

comments to create the documentation. To enable this feature, open the file Areas/HelpPage/App_Start/HelpPageConfig.cs and uncomment the following line:

```
config.SetDocumentationProvider(new XmlDocumentationProvider(
    HttpContext.Current.Server.MapPath("~/App_Data/XmlDocument.xml")));
```

Now enable XML documentation. In Solution Explorer, right-click the project and select **Properties**. Select the **Build** page.

Under **Output**, check **XML documentation file**. In the edit box, type "App_Data/XmlDocument.xml".

Next, open the code for the `ValuesController` API controller, which is defined in /Controllers/ValuesController.cs. Add some documentation comments to the controller methods. For example:

```
/// <summary>
/// Gets some very important data from the server.
/// </summary>
public IEnumerable<string> Get()
{
    return new string[] { "value1", "value2" };
}

/// <summary>
/// Looks up some data by ID.
/// </summary>
/// <param name="id">The ID of the data.</param>
public string Get(int id)
{
    return "value";
}
```

> **NOTE**
>
> Tip: If you position the caret on the line above the method and type three forward slashes, Visual Studio automatically inserts the XML elements. Then you can fill in the blanks.

Now build and run the application again, and navigate to the help pages. The documentation strings should

appear in the API table.

API	Description
GET api/Values	Gets some very important data from the server.
GET api/Values/{id}	Looks up some data by ID.

The help page reads the strings from the XML file at run time. (When you deploy the application, make sure to deploy the XML file.)

Under the Hood

The help pages are built on top of the **ApiExplorer** class, which is part of the Web API framework. The **ApiExplorer** class provides the raw material for creating a help page. For each API, **ApiExplorer** contains an **ApiDescription** that describes the API. For this purpose, an "API" is defined as the combination of HTTP method and relative URI. For example, here are some distinct APIs:

- GET /api/Products
- GET /api/Products/{id}
- POST /api/Products

If a controller action supports multiple HTTP methods, the **ApiExplorer** treats each method as a distinct API.

To hide an API from the **ApiExplorer**, add the **ApiExplorerSettings** attribute to the action and set *IgnoreApi* to true.

```
[ApiExplorerSettings(IgnoreApi=true)]
public HttpResponseMessage Get(int id) {  }
```

You can also add this attribute to the controller, to exclude the entire controller.

The ApiExplorer class gets documentation strings from the **IDocumentationProvider** interface. As you saw earlier, the Help Pages library provides an **IDocumentationProvider** that gets documentation from XML documentation strings. The code is located in /Areas/HelpPage/XmlDocumentationProvider.cs. You can get documentation from another source by writing your own **IDocumentationProvider**. To wire it up, call the **SetDocumentationProvider** extension method, defined in **HelpPageConfigurationExtensions**

ApiExplorer automatically calls into the **IDocumentationProvider** interface to get documentation strings for each API. It stores them in the **Documentation** property of the **ApiDescription** and **ApiParameterDescription** objects.

Next Steps

You aren't limited to the help pages shown here. In fact, **ApiExplorer** is not limited to creating help pages. Yao Huang Lin has written some great blog posts to get you thinking out of the box:

- Adding a simple Test Client to ASP.NET Web API Help Page
- Making ASP.NET Web API Help Page work on self-hosted services
- Design-time generation of help page (or client) for ASP.NET Web API
- Advanced Help Page customizations

Hands On Lab: Build a Single Page Application (SPA) with ASP.NET Web API and Angular.js

2/20/2020 • 22 minutes to read • Edit Online

by Web Camps Team

Download Web Camps Training Kit

This hands on lab shows you how to build a Single Page Application (SPA) with ASP.NET Web API and Angular.js for ASP.NET 4.x.

In this hand-on lab, you will take advantage of those technologies to implement Geek Quiz, a trivia website based on the SPA concept. You will first implement the service layer with ASP.NET Web API to expose the required endpoints to retrieve the quiz questions and store the answers. Then, you will build a rich and responsive UI using AngularJS and CSS3 transformation effects.

In traditional web applications, the client (browser) initiates the communication with the server by requesting a page. The server then processes the request and sends the HTML of the page to the client. In subsequent interactions with the page –e.g. the user navigates to a link or submits a form with data– a new request is sent to the server, and the flow starts again: the server processes the request and sends a new page to the browser in response to the new action requested by the client.

> In Single-Page Applications (SPAs) the entire page is loaded in the browser after the initial request, but subsequent interactions take place through Ajax requests. This means that the browser has to update only the portion of the page that has changed; there is no need to reload the entire page. The SPA approach reduces the time taken by the application to respond to user actions, resulting in a more fluid experience.
>
> The architecture of a SPA involves certain challenges that are not present in traditional web applications. However, emerging technologies like ASP.NET Web API, JavaScript frameworks like AngularJS and new styling features provided by CSS3 make it really easy to design and build SPAs.
>
> All sample code and snippets are included in the Web Camps Training Kit, available at https://aka.ms/webcamps-training-kit.

Overview

Objectives

In this hands-on lab, you will learn how to:

- Create an ASP.NET Web API service to send and receive JSON data
- Create a responsive UI using AngularJS
- Enhance the UI experience with CSS3 transformations

Prerequisites

The following is required to complete this hands-on lab:

- Visual Studio Express 2013 for Web or greater

Setup

In order to run the exercises in this hands-on lab, you will need to set up your environment first.

1. Open Windows Explorer and browse to the lab's **Source** folder.

2. Right-click on **Setup.cmd** and select **Run as administrator** to launch the setup process that will configure your environment and install the Visual Studio code snippets for this lab.
3. If the User Account Control dialog box is shown, confirm the action to proceed.

> **NOTE**
> Make sure you have checked all the dependencies for this lab before running the setup.

Using the Code Snippets

Throughout the lab document, you will be instructed to insert code blocks. For your convenience, most of this code is provided as Visual Studio Code Snippets, which you can access from within Visual Studio 2013 to avoid having to add it manually.

> **NOTE**
> Each exercise is accompanied by a starting solution located in the **Begin** folder of the exercise that allows you to follow each exercise independently of the others. Please be aware that the code snippets that are added during an exercise are missing from these starting solutions and may not work until you have completed the exercise. Inside the source code for an exercise, you will also find an **End** folder containing a Visual Studio solution with the code that results from completing the steps in the corresponding exercise. You can use these solutions as guidance if you need additional help as you work through this hands-on lab.

Exercises

This hands-on lab includes the following exercises:

1. Creating a Web API
2. Creating a SPA Interface

Estimated time to complete this lab: **60 minutes**

> **NOTE**
> When you first start Visual Studio, you must select one of the predefined settings collections. Each predefined collection is designed to match a particular development style and determines window layouts, editor behavior, IntelliSense code snippets, and dialog box options. The procedures in this lab describe the actions necessary to accomplish a given task in Visual Studio when using the **General Development Settings** collection. If you choose a different settings collection for your development environment, there may be differences in the steps that you should take into account.

Exercise 1: Creating a Web API

One of the key parts of a SPA is the service layer. It is responsible for processing the Ajax calls sent by the UI and returning data in response to that call. The data retrieved should be presented in a machine-readable format in order to be parsed and consumed by the client.

The Web API framework is part of the ASP.NET Stack and is designed to make it easy to implement HTTP services, generally sending and receiving JSON- or XML-formatted data through a RESTful API. In this exercise you will create the Web site to host the Geek Quiz application and then implement the back-end service to expose and persist the quiz data using ASP.NET Web API.

Task 1 – Creating the Initial Project for Geek Quiz

In this task you will start creating a new ASP.NET MVC project with support for ASP.NET Web API based on the **One ASP.NET** project type that comes with Visual Studio. **One ASP.NET** unifies all ASP.NET technologies and gives you the option to mix and match them as desired. You will then add the Entity Framework's model classes

and the database initializer to insert the quiz questions.

1. Open **Visual Studio Express 2013 for Web** and select **File | New Project...** to start a new solution.

Creating a New Project

2. In the **New Project** dialog box, select **ASP.NET Web Application** under the **Visual C# | Web** tab. Make sure **.NET Framework 4.5** is selected, name it *GeekQuiz*, choose a **Location** and click **OK**.

Creating a new ASP.NET Web Application project

3. In the **New ASP.NET Project** dialog box, select the **MVC** template and select the **Web API** option. Also, make sure that the **Authentication** option is set to **Individual User Accounts**. Click **OK** to continue.

Creating a new project with the MVC template, including Web API components

4. In **Solution Explorer**, right-click the **Models** folder of the **GeekQuiz** project and select **Add | Existing Item...**.

Adding an existing item

5. In the **Add Existing Item** dialog box, navigate to the **Source/Assets/Models** folder and select all the files. Click **Add**.

Adding the model assets

> **NOTE**
>
> By adding these files, you are adding the data model, the Entity Framework's database context and the database initializer for the Geek Quiz application.
>
> **Entity Framework (EF)** is an object-relational mapper (ORM) that enables you to create data access applications by programming with a conceptual application model instead of programming directly using a relational storage schema. You can learn more about Entity Framework here.
>
> The following is a description of the classes you just added:
>
> - **TriviaOption:** represents a single option associated with a quiz question
> - **TriviaQuestion:** represents a quiz question and exposes the associated options through the **Options** property
> - **TriviaAnswer:** represents the option selected by the user in response to a quiz question
> - **TriviaContext:** represents the Entity Framework's database context of the Geek Quiz application. This class derives from **DContext** and exposes **DbSet** properties that represent collections of the entities described above.
> - **TriviaDatabaseInitializer:** the implementation of the Entity Framework initializer for the **TriviaContext** class which inherits from **CreateDatabaseIfNotExists**. The default behavior of this class is to create the database only if it does not exist, inserting the entities specified in the **Seed** method.

6. Open the **Global.asax.cs** file and add the following using statement.

```
using GeekQuiz.Models;
```

7. Add the following code at the beginning of the **Application_Start** method to set the **TriviaDatabaseInitializer** as the database initializer.

```
public class MvcApplication : System.Web.HttpApplication
{
    protected void Application_Start()
    {
        System.Data.Entity.Database.SetInitializer(new TriviaDatabaseInitializer());

        AreaRegistration.RegisterAllAreas();
        GlobalConfiguration.Configure(WebApiConfig.Register);
        FilterConfig.RegisterGlobalFilters(GlobalFilters.Filters);
        RouteConfig.RegisterRoutes(RouteTable.Routes);
        BundleConfig.RegisterBundles(BundleTable.Bundles);
    }
}
```

8. Modify the **Home** controller to restrict access to authenticated users. To do this, open the **HomeController.cs** file inside the **Controllers** folder and add the **Authorize** attribute to the **HomeController** class definition.

```
namespace GeekQuiz.Controllers
{
    [Authorize]
    public class HomeController : Controller
    {
        public ActionResult Index()
        {
            return View();
        }

        ...
    }
}
```

> **NOTE**
>
> The **Authorize** filter checks to see if the user is authenticated. If the user is not authenticated, it returns HTTP status code 401 (Unauthorized) without invoking the action. You can apply the filter globally, at the controller level, or at the level of individual actions.

9. You will now customize the layout of the web pages and the branding. To do this, open the **_Layout.cshtml** file inside the **Views | Shared** folder and update the content of the **<title>** element by replacing *My ASP.NET Application* with *Geek Quiz*.

```
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0">
    <title>@ViewBag.Title - Geek Quiz</title>
    @Styles.Render("~/Content/css")
    @Scripts.Render("~/bundles/modernizr")

</head>
```

10. In the same file, update the navigation bar by removing the *About* and *Contact* links and renaming the *Home* link to *Play*. Additionally, rename the *Application name* link to *Geek Quiz*. The HTML for the navigation bar should look like the following code.

```
<div class="navbar navbar-inverse navbar-fixed-top">
    <div class="container">
        <div class="navbar-header">
            <button type="button" class="navbar-toggle" data-toggle="collapse" data-target=".navbar-
collapse">
                <span class="icon-bar"></span>
                <span class="icon-bar"></span>
                <span class="icon-bar"></span>
            </button>
            @Html.ActionLink("Geek Quiz", "Index", "Home", null, new { @class = "navbar-brand" })
        </div>
        <div class="navbar-collapse collapse">
            <ul class="nav navbar-nav">
                <li>@Html.ActionLink("Play", "Index", "Home")</li>
            </ul>
            @Html.Partial("_LoginPartial")
        </div>
    </div>
</div>
```

11. Update the footer of the layout page by replacing *My ASP.NET Application* with *Geek Quiz*. To do this, replace the content of the **<footer>** element with the following highlighted code.

```
<div class="container body-content">
    @RenderBody()
    <hr />
    <footer>
        <p>&copy; @DateTime.Now.Year - Geek Quiz</p>
    </footer>
</div>
```

Task 2 – Creating the TriviaController Web API

In the previous task, you created the initial structure of the Geek Quiz web application. You will now build a simple Web API service that interacts with the quiz data model and exposes the following actions:

- **GET /api/trivia**: Retrieves the next question from the quiz list to be answered by the authenticated user.
- **POST /api/trivia**: Stores the quiz answer specified by the authenticated user.

You will use the ASP.NET Scaffolding tools provided by Visual Studio to create the baseline for the Web API controller class.

1. Open the **WebApiConfig.cs** file inside the **App_Start** folder. This file defines the configuration of the Web API service, like how routes are mapped to Web API controller actions.

2. Add the following using statement at the beginning of the file.

```
using Newtonsoft.Json.Serialization;
```

3. Add the following highlighted code to the **Register** method to globally configure the formatter for the JSON data retrieved by the Web API action methods.

```
public static class WebApiConfig
{
    public static void Register(HttpConfiguration config)
    {
        // Web API configuration and services

        // Use camel case for JSON data.
        config.Formatters.JsonFormatter.SerializerSettings.ContractResolver = new
CamelCasePropertyNamesContractResolver();

        // Web API routes
        config.MapHttpAttributeRoutes();

        config.Routes.MapHttpRoute(
            name: "DefaultApi",
            routeTemplate: "api/{controller}/{id}",
            defaults: new { id = RouteParameter.Optional }
        );
    }
}
```

NOTE

The **CamelCasePropertyNamesContractResolver** automatically converts property names to *camel* case, which is the general convention for property names in JavaScript.

4. In **Solution Explorer**, right-click the **Controllers** folder of the **GeekQuiz** project and select **Add | New Scaffolded Item...**.

Creating a new scaffolded item

5. In the **Add Scaffold** dialog box, make sure that the **Common** node is selected in the left pane. Then, select the **Web API 2 Controller - Empty** template in the center pane and click **Add**.

Selecting the Web API 2 Controller Empty template

> **NOTE**
>
> **ASP.NET Scaffolding** is a code generation framework for ASP.NET Web applications. Visual Studio 2013 includes pre-installed code generators for MVC and Web API projects. You should use scaffolding in your project when you want to quickly add code that interacts with data models in order to reduce the amount of time required to develop standard data operations.
>
> The scaffolding process also ensures that all the required dependencies are installed in the project. For example, if you start with an empty ASP.NET project and then use scaffolding to add a Web API controller, the required Web API NuGet packages and references are added to your project automatically.

6. In the **Add Controller** dialog box, type *TriviaController* in the **Controller name** text box and click **Add**.

Adding the Trivia Controller

7. The **TriviaController.cs** file is then added to the **Controllers** folder of the **GeekQuiz** project, containing an empty **TriviaController** class. Add the following using statements at the beginning of the file.

   (Code Snippet - *AspNetWebApiSpa - Ex1 - TriviaControllerUsings*)

```
using System.Data.Entity;
using System.Threading;
using System.Threading.Tasks;
using System.Web.Http.Description;
using GeekQuiz.Models;
```

8. Add the following code at the beginning of the **TriviaController** class to define, initialize and dispose the **TriviaContext** instance in the controller.

   (Code Snippet - *AspNetWebApiSpa - Ex1 - TriviaControllerContext*)

```
public class TriviaController : ApiController
{
    private TriviaContext db = new TriviaContext();

    protected override void Dispose(bool disposing)
    {
        if (disposing)
        {
            this.db.Dispose();
        }

        base.Dispose(disposing);
    }
}
```

> **NOTE**
> The **Dispose** method of **TriviaController** invokes the **Dispose** method of the **TriviaContext** instance, which ensures that all the resources used by the context object are released when the **TriviaContext** instance is disposed or garbage-collected. This includes closing all database connections opened by Entity Framework.

9. Add the following helper method at the end of the **TriviaController** class. This method retrieves the following quiz question from the database to be answered by the specified user.

   (Code Snippet - *AspNetWebApiSpa - Ex1 - TriviaControllerNextQuestion*)

```
private async Task<TriviaQuestion> NextQuestionAsync(string userId)
{
    var lastQuestionId = await this.db.TriviaAnswers
        .Where(a => a.UserId == userId)
        .GroupBy(a => a.QuestionId)
        .Select(g => new { QuestionId = g.Key, Count = g.Count() })
        .OrderByDescending(q => new { q.Count, QuestionId = q.QuestionId })
        .Select(q => q.QuestionId)
        .FirstOrDefaultAsync();

    var questionsCount = await this.db.TriviaQuestions.CountAsync();

    var nextQuestionId = (lastQuestionId % questionsCount) + 1;
    return await this.db.TriviaQuestions.FindAsync(CancellationToken.None, nextQuestionId);
}
```

10. Add the following **Get** action method to the **TriviaController** class. This action method calls the **NextQuestionAsync** helper method defined in the previous step to retrieve the next question for the authenticated user.

    (Code Snippet - *AspNetWebApiSpa - Ex1 - TriviaControllerGetAction*)

```
// GET api/Trivia
[ResponseType(typeof(TriviaQuestion))]
public async Task<IHttpActionResult> Get()
{
    var userId = User.Identity.Name;

    TriviaQuestion nextQuestion = await this.NextQuestionAsync(userId);

    if (nextQuestion == null)
    {
        return this.NotFound();
    }

    return this.Ok(nextQuestion);
}
```

11. Add the following helper method at the end of the **TriviaController** class. This method stores the specified answer in the database and returns a Boolean value indicating whether or not the answer is correct.

    (Code Snippet - *AspNetWebApiSpa - Ex1 - TriviaControllerStoreAsync*)

```
private async Task<bool> StoreAsync(TriviaAnswer answer)
{
    this.db.TriviaAnswers.Add(answer);

    await this.db.SaveChangesAsync();
    var selectedOption = await this.db.TriviaOptions.FirstOrDefaultAsync(o => o.Id == answer.OptionId
        && o.QuestionId == answer.QuestionId);

    return selectedOption.IsCorrect;
}
```

12. Add the following **Post** action method to the **TriviaController** class. This action method associates the answer to the authenticated user and calls the **StoreAsync** helper method. Then, it sends a response with the Boolean value returned by the helper method.

    (Code Snippet - *AspNetWebApiSpa - Ex1 - TriviaControllerPostAction*)

```
// POST api/Trivia
[ResponseType(typeof(TriviaAnswer))]
public async Task<IHttpActionResult> Post(TriviaAnswer answer)
{
    if (!ModelState.IsValid)
    {
        return this.BadRequest(this.ModelState);
    }

    answer.UserId = User.Identity.Name;

    var isCorrect = await this.StoreAsync(answer);
    return this.Ok<bool>(isCorrect);
}
```

13. Modify the Web API controller to restrict access to authenticated users by adding the **Authorize** attribute to the **TriviaController** class definition.

```
[Authorize]
public class TriviaController : ApiController
{
    ...
}
```

Task 3 – Running the Solution

In this task you will verify that the Web API service you built in the previous task is working as expected. You will use the Internet Explorer **F12 Developer Tools** to capture the network traffic and inspect the full response from the Web API service.

> **NOTE**
>
> Make sure that **Internet Explorer** is selected in the **Start** button located on the Visual Studio toolbar.
>
> >

1. Press **F5** to run the solution. The **Log in** page should appear in the browser.

> **NOTE**
>
> When the application starts, the default MVC route is triggered, which by default is mapped to the **Index** action of the **HomeController** class. Since **HomeController** is restricted to authenticated users (remember that you decorated that class with the **Authorize** attribute in Exercise 1) and there is no user authenticated yet, the application redirects the original request to the log in page.

Running the solution

2. Click **Register** to create a new user.

Registering a new user

3. In the **Register** page, enter a **User name** and **Password**, and then click **Register**.

Register page

4. The application registers the new account and the user is authenticated and redirected back to the home page.

User is authenticated

5. In the browser, press **F12** to open the **Developer Tools** panel. Press **CTRL + 4** or click the **Network** icon, and then click the green arrow button to begin capturing network traffic.

Initiating Web API network capture

6. Append **api/trivia** to the URL in the browser's address bar. You will now inspect the details of the response from the **Get** action method in **TriviaController**.

Retrieving the next question data through Web API

> **NOTE**
>
> Once the download finishes, you will be prompted to make an action with the downloaded file. Leave the dialog box open in order to be able to watch the response content through the Developers Tool window.

7. Now you will inspect the body of the response. To do this, click the **Details** tab and then click **Response body**. You can check that the downloaded data is an object with the properties **options** (which is a list of **TriviaOption** objects), **id** and **title** that correspond to the **TriviaQuestion** class.

Viewing Web API Response Body

8. Go back to Visual Studio and press **SHIFT + F5** to stop debugging.

Exercise 2: Creating the SPA Interface

In this exercise you will first build the web front-end portion of Geek Quiz, focusing on the Single-Page Application interaction using **AngularJS**. You will then enhance the user experience with CSS3 to perform rich animations and provide a visual effect of context switching when transitioning from one question to the next.

Task 1 – Creating the SPA Interface Using AngularJS

In this task you will use **AngularJS** to implement the client side of the Geek Quiz application. **AngularJS** is an open-source JavaScript framework that augments browser-based applications with *Model-View-Controller* (MVC) capability, facilitating both development and testing.

You will start by installing AngularJS from Visual Studio's Package Manager Console. Then, you will create the controller to provide the behavior of the Geek Quiz app and the view to render the quiz questions and answers using the AngularJS template engine.

> **NOTE**
>
> For more information about AngularJS, refer to http://angularjs.org/.

1. Open **Visual Studio Express 2013 for Web** and open the **GeekQuiz.sln** solution located in the **Source/Ex2-CreatingASPAInterface/Begin** folder. Alternatively, you can continue with the solution that

you obtained in the previous exercise.

2. Open the **Package Manager Console** from **Tools** > **NuGet Package Manager**. Type the following command to install the **AngularJS.Core** NuGet package.

```
Install-Package AngularJS.Core
```

3. In **Solution Explorer**, right-click the **Scripts** folder of the **GeekQuiz** project and select **Add | New Folder**. Name the folder **app** and press **Enter**.

4. Right-click the **app** folder you just created and select **Add | JavaScript File**.

Creating a new JavaScript file

5. In the **Specify Name for Item** dialog box, type *quiz-controller* in the **Item name** text box and click **OK**.

Naming the new JavaScript file

6. In the **quiz-controller.js** file, add the following code to declare and initialize the AngularJS **QuizCtrl** controller.

   (Code Snippet - *AspNetWebApiSpa - Ex2 - AngularQuizController*)

```
angular.module('QuizApp', [])
    .controller('QuizCtrl', function ($scope, $http) {
        $scope.answered = false;
        $scope.title = "loading question...";
        $scope.options = [];
        $scope.correctAnswer = false;
        $scope.working = false;

        $scope.answer = function () {
            return $scope.correctAnswer ? 'correct' : 'incorrect';
        };
    });
```

> **NOTE**
>
> The constructor function of the **QuizCtrl** controller expects an injectable parameter named **$scope**. The initial state of the scope should be set up in the constructor function by attaching properties to the **$scope** object. The properties contain the **view model**, and will be accessible to the template when the controller is registered.
>
> The **QuizCtrl** controller is defined inside a module named **QuizApp**. Modules are units of work that let you break your application into separate components. The main advantages of using modules is that the code is easier to understand and facilitates unit testing, reusability and maintainability.

7. You will now add behavior to the scope in order to react to events triggered from the view. Add the following code at the end of the **QuizCtrl** controller to define the **nextQuestion** function in the **$scope** object.

   (Code Snippet - *AspNetWebApiSpa - Ex2 - AngularQuizControllerNextQuestion*)

```
.controller('QuizCtrl', function ($scope, $http) {
    ...

    $scope.nextQuestion = function () {
        $scope.working = true;
        $scope.answered = false;
        $scope.title = "loading question...";
        $scope.options = [];

        $http.get("/api/trivia").success(function (data, status, headers, config) {
            $scope.options = data.options;
            $scope.title = data.title;
            $scope.answered = false;
            $scope.working = false;
        }).error(function (data, status, headers, config) {
            $scope.title = "Oops... something went wrong";
            $scope.working = false;
        });
    };
};
```

> **NOTE**
>
> This function retrieves the next question from the **Trivia** Web API created in the previous exercise and attaches the question data to the **$scope** object.

8. Insert the following code at the end of the **QuizCtrl** controller to define the **sendAnswer** function in the **$scope** object.

   (Code Snippet - *AspNetWebApiSpa - Ex2 - AngularQuizControllerSendAnswer*)

```
.controller('QuizCtrl', function ($scope, $http) {
    ...

    $scope.sendAnswer = function (option) {
        $scope.working = true;
        $scope.answered = true;

        $http.post('/api/trivia', { 'questionId': option.questionId, 'optionId': option.id
}).success(function (data, status, headers, config) {
            $scope.correctAnswer = (data === true);
            $scope.working = false;
        }).error(function (data, status, headers, config) {
            $scope.title = "Oops... something went wrong";
            $scope.working = false;
        });
    };
};
```

> **NOTE**
>
> This function sends the answer selected by the user to the **Trivia** Web API and stores the result –i.e. if the answer is correct or not– in the **$scope** object.
>
> The **nextQuestion** and **sendAnswer** functions from above use the AngularJS **$http** object to abstract the communication with the Web API via the XMLHttpRequest JavaScript object from the browser. AngularJS supports another service that brings a higher level of abstraction to perform CRUD operations against a resource through RESTful APIs. The AngularJS **$resource** object has action methods which provide high-level behaviors without the need to interact with the **$http** object. Consider using the **$resource** object in scenarios that requires the CRUD model (fore information, see the $resource documentation).

9. The next step is to create the AngularJS template that defines the view for the quiz. To do this, open the **Index.cshtml** file inside the **Views | Home** folder and replace the content with the following code.

   (Code Snippet - *AspNetWebApiSpa - Ex2 - GeekQuizView*)

```
@{
    ViewBag.Title = "Play";
}

<div id="bodyContainer" ng-app="QuizApp">
    <section id="content">
        <div class="container" >
            <div class="row">
                <div class="flip-container text-center col-md-12" ng-controller="QuizCtrl" ng-
init="nextQuestion()">
                    <div class="back" ng-class="{flip: answered, correct: correctAnswer,
incorrect:!correctAnswer}">
                        <p class="lead">{{answer()}}</p>
                        <p>
                            <button class="btn btn-info btn-lg next option" ng-click="nextQuestion()"
ng-disabled="working">Next Question</button>
                        </p>
                    </div>
                    <div class="front" ng-class="{flip: answered}">
                        <p class="lead">{{title}}</p>
                        <div class="row text-center">
                            <button class="btn btn-info btn-lg option" ng-repeat="option in options"
ng-click="sendAnswer(option)" ng-disabled="working">{{option.title}}</button>
                        </div>
                    </div>
                </div>
            </div>
        </div>
    </section>
</div>

@section scripts {
    @Scripts.Render("~/Scripts/angular.js")
    @Scripts.Render("~/Scripts/app/quiz-controller.js")
}
```

NOTE

The AngularJS template is a declarative specification that uses information from the model and the controller to transform static markup into the dynamic view that the user sees in the browser. The following are examples of AngularJS elements and element attributes that can be used in a template:

- The **ng-app** directive tells AngularJS the DOM element that represents the root element of the application.
- The **ng-controller** directive attaches a controller to the DOM at the point where the directive is declared.
- The curly brace notation **{{ }}** denotes bindings to the scope properties defined in the controller.
- The **ng-click** directive is used to invoke the functions defined in the scope in response to user clicks.

10. Open the **Site.css** file inside the **Content** folder and add the following highlighted styles at the end of the file to provide a look and feel for the quiz view.

    (Code Snippet - *AspNetWebApiSpa - Ex2 - GeekQuizStyles*)

```
.validation-summary-valid {
     display: none;
}

/* Geek Quiz styles */
.flip-container .back,
.flip-container .front {
     border: 5px solid #00bcf2;
     padding-bottom: 30px;
     padding-top: 30px;
}

#content {
    position:relative;
    background:#fff;
    padding:50px 0 0 0;
}

.option {
     width:140px;
     margin: 5px;
}

div.correct p {
     color: green;
}

div.incorrect p {
     color: red;
}

.btn {
     border-radius: 0;
}

.flip-container div.front, .flip-container div.back.flip {
    display: block;
}

.flip-container div.front.flip, .flip-container div.back {
    display: none;
}
```

Task 2 – Running the Solution

In this task you will execute the solution using the new user interface you built with AngularJS to answer some of the quiz questions.

1. Press **F5** to run the solution.

2. Register a new user account. To do this, follow the registration steps described in Exercise 1, Task 3.

> **NOTE**
>
> If you are using the solution from the previous exercise, you can log in with the user account you created before.

3. The **Home** page should appear, showing the first question of the quiz. Answer the question by clicking one of the options. This will trigger the **sendAnswer** function defined earlier, which sends the selected option to the **Trivia** Web API.

Answering a question

4. After clicking one of the buttons, the answer should appear. Click **Next Question** to show the following question. This will trigger the **nextQuestion** function defined in the controller.

Requesting the next question

5. The next question should appear. Continue answering questions as many times as you want. After completing all the questions you should return to the first question.

Next question

6. Go back to Visual Studio and press **SHIFT + F5** to stop debugging.

Task 3 – Creating a Flip Animation Using CSS3

In this task you will use CSS3 properties to perform rich animations by adding a flip effect when a question is answered and when the next question is retrieved.

1. In **Solution Explorer**, right-click the **Content** folder of the **GeekQuiz** project and select **Add | Existing Item...**.

Adding an existing item to the Content folder

2. In the **Add Existing Item** dialog box, navigate to the **Source/Assets** folder and select **Flip.css**. Click **Add**.

Adding the Flip.css file from Assets

3. Open the **Flip.css** file you just added and inspect its content.

4. Locate the **flip transformation** comment. The styles below that comment use the CSS **perspective** and **rotateY** transformations to generate a "card flip" effect.

```
/* flip transformation */
.flip-container div.front {
    -moz-transform: perspective(2000px) rotateY(0deg);
    -webkit-transform: perspective(2000px) rotateY(0deg);
    -o-transform: perspective(2000px) rotateY(0deg);
    transform: perspective(2000px) rotateY(0deg);
}

    .flip-container div.front.flip {
        -moz-transform: perspective(2000px) rotateY(179.9deg);
        -webkit-transform: perspective(2000px) rotateY(179.9deg);
        -o-transform: perspective(2000px) rotateY(179.9deg);
        transform: perspective(2000px) rotateY(179.9deg);
    }

.flip-container div.back {
    -moz-transform: perspective(2000px) rotateY(-180deg);
    -webkit-transform: perspective(2000px) rotateY(-180deg);
    -o-transform: perspective(2000px) rotateY(-180deg);
    transform: perspective(2000px) rotateY(-180deg);
}

    .flip-container div.back.flip {
        -moz-transform: perspective(2000px) rotateY(0deg);
        -webkit-transform: perspective(2000px) rotateY(0deg);
        -ms-transform: perspective(2000px) rotateY(0);
        -o-transform: perspective(2000px) rotateY(0);
        transform: perspective(2000px) rotateY(0);
    }
```

5. Locate the **hide back of pane during flip** comment. The style below that comment hides the back-side of the faces when they are facing away from the viewer by setting the **backface-visibility** CSS property to

hidden.

```
/* hide back of pane during flip */
.front, .back {
    -moz-backface-visibility: hidden;
    -webkit-backface-visibility: hidden;
    backface-visibility: hidden;
}
```

6. Open the **BundleConfig.cs** file inside the **App_Start** folder and add the reference to the **Flip.css** file in the **"~/Content/css"** style bundle

```
bundles.Add(new StyleBundle("~/Content/css").Include(
    "~/Content/bootstrap.css",
    "~/Content/site.css",
    "~/Content/Flip.css"));
```

7. Press **F5** to run the solution and log in with your credentials.

8. Answer a question by clicking one of the options. Notice the flip effect when transitioning between views.

Answering a question with the flip effect

9. Click **Next Question** to retrieve the following question. The flip effect should appear again.

Retrieving the following question with the flip effect

Summary

By completing this hands-on lab you have learned how to:

- Create an ASP.NET Web API controller using ASP.NET Scaffolding
- Implement a Web API Get action to retrieve the next quiz question
- Implement a Web API Post action to store the quiz answers
- Install AngularJS from the Visual Studio Package Manager Console
- Implement AngularJS templates and controllers
- Use CSS3 transitions to perform animation effects

Web API Routing

2/20/2020 • 2 minutes to read • Edit Online

How ASP.NET Web API routes HTTP requests to controllers and actions.

- Routing and Action Selection in Web API
- Attribute Routing in Web API 2
- Create a REST API with Attribute Routing in Web API 2

Routing in ASP.NET Web API

2/20/2020 • 4 minutes to read • Edit Online

by Mike Wasson

This article describes how ASP.NET Web API routes HTTP requests to controllers.

> **NOTE**
>
> If you are familiar with ASP.NET MVC, Web API routing is very similar to MVC routing. The main difference is that Web API uses the HTTP verb, not the URI path, to select the action. You can also use MVC-style routing in Web API. This article does not assume any knowledge of ASP.NET MVC.

Routing Tables

In ASP.NET Web API, a *controller* is a class that handles HTTP requests. The public methods of the controller are called *action methods* or simply *actions*. When the Web API framework receives a request, it routes the request to an action.

To determine which action to invoke, the framework uses a *routing table*. The Visual Studio project template for Web API creates a default route:

```
routes.MapHttpRoute(
    name: "API Default",
    routeTemplate: "api/{controller}/{id}",
    defaults: new { id = RouteParameter.Optional }
);
```

This route is defined in the *WebApiConfig.cs* file, which is placed in the *App_Start* directory:

For more information about the `WebApiConfig` class, see Configuring ASP.NET Web API.

If you self-host Web API, you must set the routing table directly on the `HttpSelfHostConfiguration` object. For more information, see Self-Host a Web API.

Each entry in the routing table contains a *route template*. The default route template for Web API is "api/{controller}/{id}". In this template, "api" is a literal path segment, and {controller} and {id} are placeholder

variables.

When the Web API framework receives an HTTP request, it tries to match the URI against one of the route templates in the routing table. If no route matches, the client receives a 404 error. For example, the following URIs match the default route:

- /api/contacts
- /api/contacts/1
- /api/products/gizmo1

However, the following URI does not match, because it lacks the "api" segment:

- /contacts/1

> **NOTE**
> The reason for using "api" in the route is to avoid collisions with ASP.NET MVC routing. That way, you can have "/contacts" go to an MVC controller, and "/api/contacts" go to a Web API controller. Of course, if you don't like this convention, you can change the default route table.

Once a matching route is found, Web API selects the controller and the action:

- To find the controller, Web API adds "Controller" to the value of the *{controller}* variable.
- To find the action, Web API looks at the HTTP verb, and then looks for an action whose name begins with that HTTP verb name. For example, with a GET request, Web API looks for an action prefixed with "Get", such as "GetContact" or "GetAllContacts". This convention applies only to GET, POST, PUT, DELETE, HEAD, OPTIONS, and PATCH verbs. You can enable other HTTP verbs by using attributes on your controller. We'll see an example of that later.
- Other placeholder variables in the route template, such as *{id},* are mapped to action parameters.

Let's look at an example. Suppose that you define the following controller:

```
public class ProductsController : ApiController
{
    public IEnumerable<Product> GetAllProducts() { }
    public Product GetProductById(int id) { }
    public HttpResponseMessage DeleteProduct(int id){ }
}
```

Here are some possible HTTP requests, along with the action that gets invoked for each:

HTTP VERB	URI PATH	ACTION	PARAMETER
GET	api/products	GetAllProducts	*(none)*
GET	api/products/4	GetProductById	4
DELETE	api/products/4	DeleteProduct	4
POST	api/products	*(no match)*	

Notice that the *{id}* segment of the URI, if present, is mapped to the *id* parameter of the action. In this example, the controller defines two GET methods, one with an *id* parameter and one with no parameters.

Also, note that the POST request will fail, because the controller does not define a "Post..." method.

Routing Variations

The previous section described the basic routing mechanism for ASP.NET Web API. This section describes some variations.

HTTP verbs

Instead of using the naming convention for HTTP verbs, you can explicitly specify the HTTP verb for an action by decorating the action method with one of the following attributes:

- `[HttpGet]`
- `[HttpPut]`
- `[HttpPost]`
- `[HttpDelete]`
- `[HttpHead]`
- `[HttpOptions]`
- `[HttpPatch]`

In the following example, the `FindProduct` method is mapped to GET requests:

```
public class ProductsController : ApiController
{
    [HttpGet]
    public Product FindProduct(id) {}
}
```

To allow multiple HTTP verbs for an action, or to allow HTTP verbs other than GET, PUT, POST, DELETE, HEAD, OPTIONS, and PATCH, use the `[AcceptVerbs]` attribute, which takes a list of HTTP verbs.

```
public class ProductsController : ApiController
{
    [AcceptVerbs("GET", "HEAD")]
    public Product FindProduct(id) { }

    // WebDAV method
    [AcceptVerbs("MKCOL")]
    public void MakeCollection() { }
}
```

Routing by Action Name

With the default routing template, Web API uses the HTTP verb to select the action. However, you can also create a route where the action name is included in the URI:

```
routes.MapHttpRoute(
    name: "ActionApi",
    routeTemplate: "api/{controller}/{action}/{id}",
    defaults: new { id = RouteParameter.Optional }
);
```

In this route template, the *{action}* parameter names the action method on the controller. With this style of routing, use attributes to specify the allowed HTTP verbs. For example, suppose your controller has the following method:

```
public class ProductsController : ApiController
{
    [HttpGet]
    public string Details(int id);
}
```

In this case, a GET request for "api/products/details/1" would map to the `Details` method. This style of routing is similar to ASP.NET MVC, and may be appropriate for an RPC-style API.

You can override the action name by using the `[ActionName]` attribute. In the following example, there are two actions that map to "api/products/thumbnail/*id*. One supports GET and the other supports POST:

```
public class ProductsController : ApiController
{
    [HttpGet]
    [ActionName("Thumbnail")]
    public HttpResponseMessage GetThumbnailImage(int id);

    [HttpPost]
    [ActionName("Thumbnail")]
    public void AddThumbnailImage(int id);
}
```

Non-Actions

To prevent a method from getting invoked as an action, use the `[NonAction]` attribute. This signals to the framework that the method is not an action, even if it would otherwise match the routing rules.

```
// Not an action method.
[NonAction]
public string GetPrivateData() { ... }
```

Further Reading

This topic provided a high-level view of routing. For more detail, see Routing and Action Selection, which describes exactly how the framework matches a URI to a route, selects a controller, and then selects the action to invoke.

Routing and Action Selection in ASP.NET Web API

2/20/2020 • 9 minutes to read • Edit Online

by Mike Wasson

This article describes how ASP.NET Web API routes an HTTP request to a particular action on a controller.

> **NOTE**
>
> For a high-level overview of routing, see Routing in ASP.NET Web API.

This article looks at the details of the routing process. If you create a Web API project and find that some requests don't get routed the way you expect, hopefully this article will help.

Routing has three main phases:

1. Matching the URI to a route template.
2. Selecting a controller.
3. Selecting an action.

You can replace some parts of the process with your own custom behaviors. In this article, I describe the default behavior. At the end, I note the places where you can customize the behavior.

Route Templates

A route template looks similar to a URI path, but it can have placeholder values, indicated with curly braces:

```
"api/{controller}/public/{category}/{id}"
```

When you create a route, you can provide default values for some or all of the placeholders:

```
defaults: new { category = "all" }
```

You can also provide constraints, which restrict how a URI segment can match a placeholder:

```
constraints: new { id = @"\d+" }   // Only matches if "id" is one or more digits.
```

The framework tries to match the segments in the URI path to the template. Literals in the template must match exactly. A placeholder matches any value, unless you specify constraints. The framework does not match other parts of the URI, such as the host name or the query parameters. The framework selects the first route in the route table that matches the URI.

There are two special placeholders: "{controller}" and "{action}".

- "{controller}" provides the name of the controller.
- "{action}" provides the name of the action. In Web API, the usual convention is to omit "{action}".

Defaults

If you provide defaults, the route will match a URI that is missing those segments. For example:

```
routes.MapHttpRoute(
    name: "DefaultApi",
    routeTemplate: "api/{controller}/{category}",
    defaults: new { category = "all" }
);
```

The URIs `http://localhost/api/products/all` and `http://localhost/api/products` match the preceding route. In the latter URI, the missing `{category}` segment is assigned the default value `all`.

Route Dictionary

If the framework finds a match for a URI, it creates a dictionary that contains the value for each placeholder. The keys are the placeholder names, not including the curly braces. The values are taken from the URI path or from the defaults. The dictionary is stored in the **IHttpRouteData** object.

During this route-matching phase, the special "{controller}" and "{action}" placeholders are treated just like the other placeholders. They are simply stored in the dictionary with the other values.

A default can have the special value **RouteParameter.Optional**. If a placeholder gets assigned this value, the value is not added to the route dictionary. For example:

```
routes.MapHttpRoute(
    name: "DefaultApi",
    routeTemplate: "api/{controller}/{category}/{id}",
    defaults: new { category = "all", id = RouteParameter.Optional }
);
```

For the URI path "api/products", the route dictionary will contain:

- controller: "products"
- category: "all"

For "api/products/toys/123", however, the route dictionary will contain:

- controller: "products"
- category: "toys"
- id: "123"

The defaults can also include a value that does not appear anywhere in the route template. If the route matches, that value is stored in the dictionary. For example:

```
routes.MapHttpRoute(
    name: "Root",
    routeTemplate: "api/root/{id}",
    defaults: new { controller = "customers", id = RouteParameter.Optional }
);
```

If the URI path is "api/root/8", the dictionary will contain two values:

- controller: "customers"
- id: "8"

Selecting a Controller

Controller selection is handled by the **IHttpControllerSelector.SelectController** method. This method takes an **HttpRequestMessage** instance and returns an **HttpControllerDescriptor**. The default implementation is provided by the **DefaultHttpControllerSelector** class. This class uses a straightforward algorithm:

1. Look in the route dictionary for the key "controller".
2. Take the value for this key and append the string "Controller" to get the controller type name.
3. Look for a Web API controller with this type name.

For example, if the route dictionary contains the key-value pair "controller" = "products", then the controller type is "ProductsController". If there is no matching type, or multiple matches, the framework returns an error to the client.

For step 3, **DefaultHttpControllerSelector** uses the **IHttpControllerTypeResolver** interface to get the list of Web API controller types. The default implementation of **IHttpControllerTypeResolver** returns all public classes that (a) implement **IHttpController**, (b) are not abstract, and (c) have a name that ends in "Controller".

Action Selection

After selecting the controller, the framework selects the action by calling the **IHttpActionSelector.SelectAction** method. This method takes an **HttpControllerContext** and returns an **HttpActionDescriptor**.

The default implementation is provided by the **ApiControllerActionSelector** class. To select an action, it looks at the following:

- The HTTP method of the request.
- The "{action}" placeholder in the route template, if present.
- The parameters of the actions on the controller.

Before looking at the selection algorithm, we need to understand some things about controller actions.

Which methods on the controller are considered "actions"? When selecting an action, the framework only looks at public instance methods on the controller. Also, it excludes "special name" methods (constructors, events, operator overloads, and so forth), and methods inherited from the **ApiController** class.

HTTP Methods. The framework only chooses actions that match the HTTP method of the request, determined as follows:

1. You can specify the HTTP method with an attribute: **AcceptVerbs**, **HttpDelete**, **HttpGet**, **HttpHead**, **HttpOptions**, **HttpPatch**, **HttpPost**, or **HttpPut**.
2. Otherwise, if the name of the controller method starts with "Get", "Post", "Put", "Delete", "Head", "Options", or "Patch", then by convention the action supports that HTTP method.
3. If none of the above, the method supports POST.

Parameter Bindings. A parameter binding is how Web API creates a value for a parameter. Here is the default rule for parameter binding:

- Simple types are taken from the URI.
- Complex types are taken from the request body.

Simple types include all of the .NET Framework primitive types, plus **DateTime**, **Decimal**, **Guid**, **String**, and **TimeSpan**. For each action, at most one parameter can read the request body.

> **NOTE**
>
> It is possible to override the default binding rules. See WebAPI Parameter binding under the hood.

With that background, here is the action selection algorithm.

1. Create a list of all actions on the controller that match the HTTP request method.

2. If the route dictionary has an "action" entry, remove actions whose name does not match this value.

3. Try to match action parameters to the URI, as follows:
    a. For each action, get a list of the parameters that are a simple type, where the binding gets the parameter from the URI. Exclude optional parameters.
    b. From this list, try to find a match for each parameter name, either in the route dictionary or in the URI query string. Matches are case insensitive and do not depend on the parameter order.
    c. Select an action where every parameter in the list has a match in the URI.
    d. If more that one action meets these criteria, pick the one with the most parameter matches.
4. Ignore actions with the **[NonAction]** attribute.

Step #3 is probably the most confusing. The basic idea is that a parameter can get its value either from the URI, from the request body, or from a custom binding. For parameters that come from the URI, we want to ensure that the URI actually contains a value for that parameter, either in the path (via the route dictionary) or in the query string.

For example, consider the following action:

```
public void Get(int id)
```

The *id* parameter binds to the URI. Therefore, this action can only match a URI that contains a value for "id", either in the route dictionary or in the query string.

Optional parameters are an exception, because they are optional. For an optional parameter, it's OK if the binding can't get the value from the URI.

Complex types are an exception for a different reason. A complex type can only bind to the URI through a custom binding. But in that case, the framework cannot know in advance whether the parameter would bind to a particular URI. To find out, it would need to invoke the binding. The goal of the selection algorithm is to select an action from the static description, before invoking any bindings. Therefore, complex types are excluded from the matching algorithm.

After the action is selected, all parameter bindings are invoked.

Summary:

- The action must match the HTTP method of the request.
- The action name must match the "action" entry in the route dictionary, if present.
- For every parameter of the action, if the parameter is taken from the URI, then the parameter name must be found either in the route dictionary or in the URI query string. (Optional parameters and parameters with complex types are excluded.)
- Try to match the most number of parameters. The best match might be a method with no parameters.

Extended Example

Routes:

```
routes.MapHttpRoute(
    name: "ApiRoot",
    routeTemplate: "api/root/{id}",
    defaults: new { controller = "products", id = RouteParameter.Optional }
);
routes.MapHttpRoute(
    name: "DefaultApi",
    routeTemplate: "api/{controller}/{id}",
    defaults: new { id = RouteParameter.Optional }
);
```

Controller:

```
public class ProductsController : ApiController
{
    public IEnumerable<Product> GetAll() {}
    public Product GetById(int id, double version = 1.0) {}
    [HttpGet]
    public void FindProductsByName(string name) {}
    public void Post(Product value) {}
    public void Put(int id, Product value) {}
}
```

HTTP request:

```
GET http://localhost:34701/api/products/1?version=1.5&details=1
```

Route Matching

The URI matches the route named "DefaultApi". The route dictionary contains the following entries:

- controller: "products"
- id: "1"

The route dictionary does not contain the query string parameters, "version" and "details", but these will still be considered during action selection.

Controller Selection

From the "controller" entry in the route dictionary, the controller type is `ProductsController`.

Action Selection

The HTTP request is a GET request. The controller actions that support GET are `GetAll`, `GetById`, and `FindProductsByName`. The route dictionary does not contain an entry for "action", so we don't need to match the action name.

Next, we try to match parameter names for the actions, looking only at the GET actions.

ACTION	PARAMETERS TO MATCH
`GetAll`	none
`GetById`	"id"
`FindProductsByName`	"name"

Notice that the *version* parameter of `GetById` is not considered, because it is an optional parameter.

The `GetAll` method matches trivially. The `GetById` method also matches, because the route dictionary contains "id". The `FindProductsByName` method does not match.

The `GetById` method wins, because it matches one parameter, versus no parameters for `GetAll`. The method is invoked with the following parameter values:

- *id* = 1
- *version* = 1.5

Notice that even though *version* was not used in the selection algorithm, the value of the parameter comes from the URI query string.

Extension Points

Web API provides extension points for some parts of the routing process.

INTERFACE	DESCRIPTION
IHttpControllerSelector	Selects the controller.
IHttpControllerTypeResolver	Gets the list of controller types. The **DefaultHttpControllerSelector** chooses the controller type from this list.
IAssembliesResolver	Gets the list of project assemblies. The **IHttpControllerTypeResolver** interface uses this list to find the controller types.
IHttpControllerActivator	Creates new controller instances.
IHttpActionSelector	Selects the action.
IHttpActionInvoker	Invokes the action.

To provide your own implementation for any of these interfaces, use the **Services** collection on the **HttpConfiguration** object:

```
var config = GlobalConfiguration.Configuration;
config.Services.Replace(typeof(IHttpControllerSelector), new MyControllerSelector(config));
```

Attribute Routing in ASP.NET Web API 2

4/6/2020 • 10 minutes to read • Edit Online

by Mike Wasson

Routing is how Web API matches a URI to an action. Web API 2 supports a new type of routing, called *attribute routing*. As the name implies, attribute routing uses attributes to define routes. Attribute routing gives you more control over the URIs in your web API. For example, you can easily create URIs that describe hierarchies of resources.

The earlier style of routing, called convention-based routing, is still fully supported. In fact, you can combine both techniques in the same project.

This topic shows how to enable attribute routing and describes the various options for attribute routing. For an end-to-end tutorial that uses attribute routing, see Create a REST API with Attribute Routing in Web API 2.

Prerequisites

Visual Studio 2017 Community, Professional, or Enterprise edition

Alternatively, use NuGet Package Manager to install the necessary packages. From the **Tools** menu in Visual Studio, select **NuGet Package Manager**, then select **Package Manager Console**. Enter the following command in the Package Manager Console window:

```
Install-Package Microsoft.AspNet.WebApi.WebHost
```

Why Attribute Routing?

The first release of Web API used *convention-based* routing. In that type of routing, you define one or more route templates, which are basically parameterized strings. When the framework receives a request, it matches the URI against the route template. For more information about convention-based routing, see Routing in ASP.NET Web API.

One advantage of convention-based routing is that templates are defined in a single place, and the routing rules are applied consistently across all controllers. Unfortunately, convention-based routing makes it hard to support certain URI patterns that are common in RESTful APIs. For example, resources often contain child resources: Customers have orders, movies have actors, books have authors, and so forth. It's natural to create URIs that reflect these relations:

```
/customers/1/orders
```

This type of URI is difficult to create using convention-based routing. Although it can be done, the results don't scale well if you have many controllers or resource types.

With attribute routing, it's trivial to define a route for this URI. You simply add an attribute to the controller action:

```
[Route("customers/{customerId}/orders")]
public IEnumerable<Order> GetOrdersByCustomer(int customerId) { ... }
```

Here are some other patterns that attribute routing makes easy.

API versioning

In this example, "/api/v1/products" would be routed to a different controller than "/api/v2/products".

`/api/v1/products` `/api/v2/products`

Overloaded URI segments

In this example, "1" is an order number, but "pending" maps to a collection.

`/orders/1` `/orders/pending`

Multiple parameter types

In this example, "1" is an order number, but "2013/06/16" specifies a date.

`/orders/1` `/orders/2013/06/16`

Enabling Attribute Routing

To enable attribute routing, call **MapHttpAttributeRoutes** during configuration. This extension method is defined in the **System.Web.Http.HttpConfigurationExtensions** class.

```
using System.Web.Http;

namespace WebApplication
{
    public static class WebApiConfig
    {
        public static void Register(HttpConfiguration config)
        {
            // Web API routes
            config.MapHttpAttributeRoutes();

            // Other Web API configuration not shown.
        }
    }
}
```

Attribute routing can be combined with convention-based routing. To define convention-based routes, call the **MapHttpRoute** method.

```
public static class WebApiConfig
{
    public static void Register(HttpConfiguration config)
    {
        // Attribute routing.
        config.MapHttpAttributeRoutes();

        // Convention-based routing.
        config.Routes.MapHttpRoute(
            name: "DefaultApi",
            routeTemplate: "api/{controller}/{id}",
            defaults: new { id = RouteParameter.Optional }
        );
    }
}
```

For more information about configuring Web API, see Configuring ASP.NET Web API 2.

Note: Migrating From Web API 1

Prior to Web API 2, the Web API project templates generated code like this:

```
protected void Application_Start()
{
    // WARNING - Not compatible with attribute routing.
    WebApiConfig.Register(GlobalConfiguration.Configuration);
}
```

If attribute routing is enabled, this code will throw an exception. If you upgrade an existing Web API project to use attribute routing, make sure to update this configuration code to the following:

```
protected void Application_Start()
{
    // Pass a delegate to the Configure method.
    GlobalConfiguration.Configure(WebApiConfig.Register);
}
```

> **NOTE**
>
> For more information, see Configuring Web API with ASP.NET Hosting.

Adding Route Attributes

Here is an example of a route defined using an attribute:

```
public class OrdersController : ApiController
{
    [Route("customers/{customerId}/orders")]
    [HttpGet]
    public IEnumerable<Order> FindOrdersByCustomer(int customerId) { ... }
}
```

The string "customers/{customerId}/orders" is the URI template for the route. Web API tries to match the request URI to the template. In this example, "customers" and "orders" are literal segments, and "{customerId}" is a variable parameter. The following URIs would match this template:

- `http://localhost/customers/1/orders`
- `http://localhost/customers/bob/orders`
- `http://localhost/customers/1234-5678/orders`

You can restrict the matching by using constraints, described later in this topic.

Notice that the "{customerId}" parameter in the route template matches the name of the *customerId* parameter in the method. When Web API invokes the controller action, it tries to bind the route parameters. For example, if the URI is `http://example.com/customers/1/orders`, Web API tries to bind the value "1" to the *customerId* parameter in the action.

A URI template can have several parameters:

```
[Route("customers/{customerId}/orders/{orderId}")]
public Order GetOrderByCustomer(int customerId, int orderId) { ... }
```

Any controller methods that do not have a route attribute use convention-based routing. That way, you can combine both types of routing in the same project.

HTTP Methods

Web API also selects actions based on the HTTP method of the request (GET, POST, etc). By default, Web API looks for a case-insensitive match with the start of the controller method name. For example, a controller method named `PutCustomers` matches an HTTP PUT request.

You can override this convention by decorating the method with any the following attributes:

- **[HttpDelete]**
- **[HttpGet]**
- **[HttpHead]**
- **[HttpOptions]**
- **[HttpPatch]**
- **[HttpPost]**
- **[HttpPut]**

The following example maps the CreateBook method to HTTP POST requests.

```
[Route("api/books")]
[HttpPost]
public HttpResponseMessage CreateBook(Book book) { ... }
```

For all other HTTP methods, including non-standard methods, use the **AcceptVerbs** attribute, which takes a list of HTTP methods.

```
// WebDAV method
[Route("api/books")]
[AcceptVerbs("MKCOL")]
public void MakeCollection() { }
```

Route Prefixes

Often, the routes in a controller all start with the same prefix. For example:

```
public class BooksController : ApiController
{
    [Route("api/books")]
    public IEnumerable<Book> GetBooks() { ... }

    [Route("api/books/{id:int}")]
    public Book GetBook(int id) { ... }

    [Route("api/books")]
    [HttpPost]
    public HttpResponseMessage CreateBook(Book book) { ... }
}
```

You can set a common prefix for an entire controller by using the **[RoutePrefix]** attribute:

```
[RoutePrefix("api/books")]
public class BooksController : ApiController
{
    // GET api/books
    [Route("")]
    public IEnumerable<Book> Get() { ... }

    // GET api/books/5
    [Route("{id:int}")]
    public Book Get(int id) { ... }

    // POST api/books
    [Route("")]
    public HttpResponseMessage Post(Book book) { ... }
}
```

Use a tilde (~) on the method attribute to override the route prefix:

```
[RoutePrefix("api/books")]
public class BooksController : ApiController
{
    // GET /api/authors/1/books
    [Route("~/api/authors/{authorId:int}/books")]
    public IEnumerable<Book> GetByAuthor(int authorId) { ... }

    // ...
}
```

The route prefix can include parameters:

```
[RoutePrefix("customers/{customerId}")]
public class OrdersController : ApiController
{
    // GET customers/1/orders
    [Route("orders")]
    public IEnumerable<Order> Get(int customerId) { ... }
}
```

Route Constraints

Route constraints let you restrict how the parameters in the route template are matched. The general syntax is "{parameter:constraint}". For example:

```
[Route("users/{id:int}")]
public User GetUserById(int id) { ... }

[Route("users/{name}")]
public User GetUserByName(string name) { ... }
```

Here, the first route will only be selected if the "id" segment of the URI is an integer. Otherwise, the second route will be chosen.

The following table lists the constraints that are supported.

CONSTRAINT	DESCRIPTION	EXAMPLE
alpha	Matches uppercase or lowercase Latin alphabet characters (a-z, A-Z)	{x:alpha}

CONSTRAINT	DESCRIPTION	EXAMPLE
bool	Matches a Boolean value.	{x:bool}
datetime	Matches a **DateTime** value.	{x:datetime}
decimal	Matches a decimal value.	{x:decimal}
double	Matches a 64-bit floating-point value.	{x:double}
float	Matches a 32-bit floating-point value.	{x:float}
guid	Matches a GUID value.	{x:guid}
int	Matches a 32-bit integer value.	{x:int}
length	Matches a string with the specified length or within a specified range of lengths.	{x:length(6)} {x:length(1,20)}
long	Matches a 64-bit integer value.	{x:long}
max	Matches an integer with a maximum value.	{x:max(10)}
maxlength	Matches a string with a maximum length.	{x:maxlength(10)}
min	Matches an integer with a minimum value.	{x:min(10)}
minlength	Matches a string with a minimum length.	{x:minlength(10)}
range	Matches an integer within a range of values.	{x:range(10,50)}
regex	Matches a regular expression.	{x:regex(^\d{3}-\d{3}-\d{4}$)}

Notice that some of the constraints, such as "min", take arguments in parentheses. You can apply multiple constraints to a parameter, separated by a colon.

```
[Route("users/{id:int:min(1)}")]
public User GetUserById(int id) { ... }
```

Custom Route Constraints

You can create custom route constraints by implementing the **IHttpRouteConstraint** interface. For example, the following constraint restricts a parameter to a non-zero integer value.

```
public class NonZeroConstraint : IHttpRouteConstraint
{
    public bool Match(HttpRequestMessage request, IHttpRoute route, string parameterName,
        IDictionary<string, object> values, HttpRouteDirection routeDirection)
    {
        object value;
        if (values.TryGetValue(parameterName, out value) && value != null)
        {
            long longValue;
            if (value is long)
            {
                longValue = (long)value;
                return longValue != 0;
            }

            string valueString = Convert.ToString(value, CultureInfo.InvariantCulture);
            if (Int64.TryParse(valueString, NumberStyles.Integer,
                CultureInfo.InvariantCulture, out longValue))
            {
                return longValue != 0;
            }
        }
        return false;
    }
}
```

The following code shows how to register the constraint:

```
public static class WebApiConfig
{
    public static void Register(HttpConfiguration config)
    {
        var constraintResolver = new DefaultInlineConstraintResolver();
        constraintResolver.ConstraintMap.Add("nonzero", typeof(NonZeroConstraint));

        config.MapHttpAttributeRoutes(constraintResolver);
    }
}
```

Now you can apply the constraint in your routes:

```
[Route("{id:nonzero}")]
public HttpResponseMessage GetNonZero(int id) { ... }
```

You can also replace the entire **DefaultInlineConstraintResolver** class by implementing the **IInlineConstraintResolver** interface. Doing so will replace all of the built-in constraints, unless your implementation of **IInlineConstraintResolver** specifically adds them.

Optional URI Parameters and Default Values

You can make a URI parameter optional by adding a question mark to the route parameter. If a route parameter is optional, you must define a default value for the method parameter.

```
public class BooksController : ApiController
{
    [Route("api/books/locale/{lcid:int?}")]
    public IEnumerable<Book> GetBooksByLocale(int lcid = 1033) { ... }
}
```

In this example, `/api/books/locale/1033` and `/api/books/locale` return the same resource.

Alternatively, you can specify a default value inside the route template, as follows:

```
public class BooksController : ApiController
{
    [Route("api/books/locale/{lcid:int=1033}")]
    public IEnumerable<Book> GetBooksByLocale(int lcid) { ... }
}
```

This is almost the same as the previous example, but there is a slight difference of behavior when the default value is applied.

- In the first example ("{lcid:int?}"), the default value of 1033 is assigned directly to the method parameter, so the parameter will have this exact value.
- In the second example ("{lcid:int=1033}"), the default value of "1033" goes through the model-binding process. The default model-binder will convert "1033" to the numeric value 1033. However, you could plug in a custom model binder, which might do something different.

(In most cases, unless you have custom model binders in your pipeline, the two forms will be equivalent.)

Route Names

In Web API, every route has a name. Route names are useful for generating links, so that you can include a link in an HTTP response.

To specify the route name, set the **Name** property on the attribute. The following example shows how to set the route name, and also how to use the route name when generating a link.

```
public class BooksController : ApiController
{
    [Route("api/books/{id}", Name="GetBookById")]
    public BookDto GetBook(int id)
    {
        // Implementation not shown...
    }

    [Route("api/books")]
    public HttpResponseMessage Post(Book book)
    {
        // Validate and add book to database (not shown)

        var response = Request.CreateResponse(HttpStatusCode.Created);

        // Generate a link to the new book and set the Location header in the response.
        string uri = Url.Link("GetBookById", new { id = book.BookId });
        response.Headers.Location = new Uri(uri);
        return response;
    }
}
```

Route Order

When the framework tries to match a URI with a route, it evaluates the routes in a particular order. To specify the order, set the **Order** property on the route attribute. Lower values are evaluated first. The default order value is zero.

Here is how the total ordering is determined:

1. Compare the **Order** property of the route attribute.
2. Look at each URI segment in the route template. For each segment, order as follows:
   a. Literal segments.
   b. Route parameters with constraints.
   c. Route parameters without constraints.
   d. Wildcard parameter segments with constraints.
   e. Wildcard parameter segments without constraints.
3. In the case of a tie, routes are ordered by a case-insensitive ordinal string comparison (OrdinalIgnoreCase) of the route template.

Here is an example. Suppose you define the following controller:

```
[RoutePrefix("orders")]
public class OrdersController : ApiController
{
    [Route("{id:int}")] // constrained parameter
    public HttpResponseMessage Get(int id) { ... }

    [Route("details")]  // literal
    public HttpResponseMessage GetDetails() { ... }

    [Route("pending", RouteOrder = 1)]
    public HttpResponseMessage GetPending() { ... }

    [Route("{customerName}")]  // unconstrained parameter
    public HttpResponseMessage GetByCustomer(string customerName) { ... }

    [Route("{*date:datetime}")]  // wildcard
    public HttpResponseMessage Get(DateTime date) { ... }
}
```

These routes are ordered as follows.

1. orders/details
2. orders/{id}
3. orders/{customerName}
4. orders/{*date}
5. orders/pending

Notice that "details" is a literal segment and appears before "{id}", but "pending" appears last because the **Order** property is 1. (This example assumes there are no customers named "details" or "pending". In general, try to avoid ambiguous routes. In this example, a better route template for `GetByCustomer` is "customers/{customerName}")

Create a REST API with Attribute Routing in ASP.NET Web API 2

9/16/2020 • 11 minutes to read • Edit Online

by Mike Wasson

Web API 2 supports a new type of routing, called *attribute routing*. For a general overview of attribute routing, see Attribute Routing in Web API 2. In this tutorial, you will use attribute routing to create a REST API for a collection of books. The API will support the following actions:

ACTION	EXAMPLE URI
Get a list of all books.	/api/books
Get a book by ID.	/api/books/1
Get the details of a book.	/api/books/1/details
Get a list of books by genre.	/api/books/fantasy
Get a list of books by publication date.	/api/books/date/2013-02-16 /api/books/date/2013/02/16 (alternate form)
Get a list of books by a particular author.	/api/authors/1/books

All methods are read-only (HTTP GET requests).

For the data layer, we'll use Entity Framework. Book records will have the following fields:

- ID
- Title
- Genre
- Publication date
- Price
- Description
- AuthorID (foreign key to an Authors table)

For most requests, however, the API will return a subset of this data (title, author, and genre). To get the complete record, the client requests `/api/books/{id}/details`.

Prerequisites

Visual Studio 2017 Community, Professional or Enterprise edition.

Create the Visual Studio Project

Start by running Visual Studio. From the **File** menu, select **New** and then select **Project**.

Expand the **Installed** > **Visual C#** category. Under **Visual C#**, select **Web**. In the list of project templates, select **ASP.NET Web Application (.NET Framework)**. Name the project "BooksAPI".

In the **New ASP.NET Web Application** dialog, select the **Empty** template. Under "Add folders and core references for", select the **Web API** checkbox. Click **OK**.

This creates a skeleton project that is configured for Web API functionality.

Domain Models

Next, add classes for domain models. In Solution Explorer, right-click the Models folder. Select **Add**, then select **Class**. Name the class `Author`.

Replace the code in Author.cs with the following:

```
using System.ComponentModel.DataAnnotations;

namespace BooksAPI.Models
{
    public class Author
    {
        public int AuthorId { get; set; }
        [Required]
        public string Name { get; set; }
    }
}
```

Now add another class named `Book`.

```
using System;
using System.ComponentModel.DataAnnotations;
using System.ComponentModel.DataAnnotations.Schema;

namespace BooksAPI.Models
{
    public class Book
    {
        public int BookId { get; set; }
        [Required]
        public string Title { get; set; }
        public decimal Price { get; set; }
        public string Genre { get; set; }
        public DateTime PublishDate { get; set; }
        public string Description { get; set; }
        public int AuthorId { get; set; }
        [ForeignKey("AuthorId")]
        public Author Author { get; set; }
    }
}
```

Add a Web API Controller

In this step, we'll add a Web API controller that uses Entity Framework as the data layer.

Press CTRL+SHIFT+B to build the project. Entity Framework uses reflection to discover the properties of the models, so it requires a compiled assembly to create the database schema.

In Solution Explorer, right-click the Controllers folder. Select **Add**, then select **Controller**.

In the **Add Scaffold** dialog, select **Web API 2 Controller with actions, using Entity Framework**.

In the **Add Controller** dialog, for **Controller name**, enter "BooksController". Select the "Use async controller actions" checkbox. For **Model class**, select "Book". (If you don't see the `Book` class listed in the dropdown, make sure that you built the project.) Then click the "+" button.

Click **Add** in the **New Data Context** dialog.

Click **Add** in the **Add Controller** dialog. The scaffolding adds a class named `BooksController` that defines the API controller. It also adds a class named `BooksAPIContext` in the Models folder, which defines the data context for Entity Framework.

Seed the Database

From the Tools menu, select **NuGet Package Manager**, and then select **Package Manager Console**.

In the Package Manager Console window, enter the following command:

```
Add-Migration
```

This command creates a Migrations folder and adds a new code file named Configuration.cs. Open this file and add the following code to the `Configuration.Seed` method.

```
protected override void Seed(BooksAPI.Models.BooksAPIContext context)
{
    context.Authors.AddOrUpdate(new Author[] {
        new Author() { AuthorId = 1, Name = "Ralls, Kim" },
        new Author() { AuthorId = 2, Name = "Corets, Eva" },
        new Author() { AuthorId = 3, Name = "Randall, Cynthia" },
        new Author() { AuthorId = 4, Name = "Thurman, Paula" }
        });

    context.Books.AddOrUpdate(new Book[] {
        new Book() { BookId = 1,  Title= "Midnight Rain", Genre = "Fantasy",
        PublishDate = new DateTime(2000, 12, 16), AuthorId = 1, Description =
        "A former architect battles an evil sorceress.", Price = 14.95M },

        new Book() { BookId = 2, Title = "Maeve Ascendant", Genre = "Fantasy",
            PublishDate = new DateTime(2000, 11, 17), AuthorId = 2, Description =
            "After the collapse of a nanotechnology society, the young" +
            "survivors lay the foundation for a new society.", Price = 12.95M },

        new Book() { BookId = 3, Title = "The Sundered Grail", Genre = "Fantasy",
            PublishDate = new DateTime(2001, 09, 10), AuthorId = 2, Description =
            "The two daughters of Maeve battle for control of England.", Price = 12.95M },

        new Book() { BookId = 4, Title = "Lover Birds", Genre = "Romance",
            PublishDate = new DateTime(2000, 09, 02), AuthorId = 3, Description =
            "When Carla meets Paul at an ornithology conference, tempers fly.", Price = 7.99M },

        new Book() { BookId = 5, Title = "Splish Splash", Genre = "Romance",
            PublishDate = new DateTime(2000, 11, 02), AuthorId = 4, Description =
            "A deep sea diver finds true love 20,000 leagues beneath the sea.", Price = 6.99M},
    });
}
```

In the Package Manager Console window, type the following commands.

```
add-migration Initial

update-database
```

These commands create a local database and invoke the Seed method to populate the database.

Add DTO Classes

If you run the application now and send a GET request to /api/books/1, the response looks similar to the following. (I added indentation for readability.)

```
{
  "BookId": 1,
  "Title": "Midnight Rain",
  "Genre": "Fantasy",
  "PublishDate": "2000-12-16T00:00:00",
  "Description": "A former architect battles an evil sorceress.",
  "Price": 14.95,
  "AuthorId": 1,
  "Author": null
}
```

Instead, I want this request to return a subset of the fields. Also, I want it to return the author's name, rather than the author ID. To accomplish this, we'll modify the controller methods to return a *data transfer object* (DTO) instead of the EF model. A DTO is an object that is designed only to carry data.

In Solution Explorer, right-click the project and select **Add | New Folder**. Name the folder "DTOs". Add a class named `BookDto` to the DTOs folder, with the following definition:

```
namespace BooksAPI.DTOs
{
    public class BookDto
    {
        public string Title { get; set; }
        public string Author { get; set; }
        public string Genre { get; set; }
    }
}
```

Add another class named `BookDetailDto`.

```
using System;

namespace BooksAPI.DTOs
{
    public class BookDetailDto
    {
        public string Title { get; set; }
        public string Genre { get; set; }
        public DateTime PublishDate { get; set; }
        public string Description { get; set; }
        public decimal Price { get; set; }
        public string Author { get; set; }
    }
}
```

Next, update the `BooksController` class to return `BookDto` instances. We'll use the Queryable.Select method to project `Book` instances to `BookDto` instances. Here is the updated code for the controller class.

```
using BooksAPI.DTOs;
using BooksAPI.Models;
using System;
using System.Data.Entity;
using System.Linq;
using System.Linq.Expressions;
using System.Threading.Tasks;
using System.Web.Http;
using System.Web.Http.Description;

namespace BooksAPI.Controllers
{
    public class BooksController : ApiController
    {
        private BooksAPIContext db = new BooksAPIContext();

        // Typed lambda expression for Select() method.
        private static readonly Expression<Func<Book, BookDto>> AsBookDto =
            x => new BookDto
            {
                Title = x.Title,
                Author = x.Author.Name,
                Genre = x.Genre
            };

        // GET api/Books
        public IQueryable<BookDto> GetBooks()
        {
            return db.Books.Include(b => b.Author).Select(AsBookDto);
        }

        // GET api/Books/5
        [ResponseType(typeof(BookDto))]
        public async Task<IHttpActionResult> GetBook(int id)
        {
            BookDto book = await db.Books.Include(b => b.Author)
                .Where(b => b.BookId == id)
                .Select(AsBookDto)
                .FirstOrDefaultAsync();
            if (book == null)
            {
                return NotFound();
            }

            return Ok(book);
        }

        protected override void Dispose(bool disposing)
        {
            db.Dispose();
            base.Dispose(disposing);
        }
    }
}
```

NOTE

I deleted the `PutBook`, `PostBook`, and `DeleteBook` methods, because they aren't needed for this tutorial.

Now if you run the application and request /api/books/1, the response body should look like this:

```
{"Title":"Midnight Rain","Author":"Ralls, Kim","Genre":"Fantasy"}
```

Add Route Attributes

Next, we'll convert the controller to use attribute routing. First, add a **RoutePrefix** attribute to the controller. This attribute defines the initial URI segments for all methods on this controller.

```
[RoutePrefix("api/books")]
public class BooksController : ApiController
{
    // ...
```

Then add **[Route]** attributes to the controller actions, as follows:

```
[Route("")]
public IQueryable<BookDto> GetBooks()
{
    // ...
}

[Route("{id:int}")]
[ResponseType(typeof(BookDto))]
public async Task<IHttpActionResult> GetBook(int id)
{
    // ...
}
```

The route template for each controller method is the prefix plus the string specified in the **Route** attribute. For the `GetBook` method, the route template includes the parameterized string "{id:int}", which matches if the URI segment contains an integer value.

METHOD	ROUTE TEMPLATE	EXAMPLE URI
`GetBooks`	"api/books"	`http://localhost/api/books`
`GetBook`	"api/books/{id:int}"	`http://localhost/api/books/5`

Get Book Details

To get book details, the client will send a GET request to `/api/books/{id}/details`, where *{id}* is the ID of the book.

Add the following method to the `BooksController` class.

```
[Route("{id:int}/details")]
[ResponseType(typeof(BookDetailDto))]
public async Task<IHttpActionResult> GetBookDetail(int id)
{
    var book = await (from b in db.Books.Include(b => b.Author)
                where b.BookId == id
                select new BookDetailDto
                {
                    Title = b.Title,
                    Genre = b.Genre,
                    PublishDate = b.PublishDate,
                    Price = b.Price,
                    Description = b.Description,
                    Author = b.Author.Name
                }).FirstOrDefaultAsync();

    if (book == null)
    {
        return NotFound();
    }
    return Ok(book);
}
```

If you request `/api/books/1/details`, the response looks like this:

```
{
  "Title": "Midnight Rain",
  "Genre": "Fantasy",
  "PublishDate": "2000-12-16T00:00:00",
  "Description": "A former architect battles an evil sorceress.",
  "Price": 14.95,
  "Author": "Ralls, Kim"
}
```

Get Books By Genre

To get a list of books in a specific genre, the client will send a GET request to `/api/books/genre`, where *genre* is the name of the genre. (For example, `/api/books/fantasy`.)

Add the following method to `BooksController`.

```
[Route("{genre}")]
public IQueryable<BookDto> GetBooksByGenre(string genre)
{
    return db.Books.Include(b => b.Author)
        .Where(b => b.Genre.Equals(genre, StringComparison.OrdinalIgnoreCase))
        .Select(AsBookDto);
}
```

Here we are defining a route that contains a {genre} parameter in the URI template. Notice that Web API is able to distinguish these two URIs and route them to different methods:

`/api/books/1`

`/api/books/fantasy`

That's because the `GetBook` method includes a constraint that the "id" segment must be an integer value:

```
[Route("{id:int}")]
public BookDto GetBook(int id)
{
    // ...
}
```

If you request /api/books/fantasy, the response looks like this:

```
[ { "Title": "Midnight Rain", "Author": "Ralls, Kim", "Genre": "Fantasy" }, { "Title": "Maeve Ascendant",
"Author": "Corets, Eva", "Genre": "Fantasy" }, { "Title": "The Sundered Grail", "Author": "Corets, Eva",
"Genre": "Fantasy" } ]
```

Get Books By Author

To get a list of a books for a particular author, the client will send a GET request to `/api/authors/id/books`, where *id* is the ID of the author.

Add the following method to `BooksController`.

```
[Route("~/api/authors/{authorId:int}/books")]
public IQueryable<BookDto> GetBooksByAuthor(int authorId)
{
    return db.Books.Include(b => b.Author)
        .Where(b => b.AuthorId == authorId)
        .Select(AsBookDto);
}
```

This example is interesting because "books" is treated a child resource of "authors". This pattern is quite common in RESTful APIs.

The tilde (~) in the route template overrides the route prefix in the **RoutePrefix** attribute.

Get Books By Publication Date

To get a list of books by publication date, the client will send a GET request to `/api/books/date/yyyy-mm-dd`, where *yyyy-mm-dd* is the date.

Here is one way to do this:

```
[Route("date/{pubdate:datetime}")]
public IQueryable<BookDto> GetBooks(DateTime pubdate)
{
    return db.Books.Include(b => b.Author)
        .Where(b => DbFunctions.TruncateTime(b.PublishDate)
            == DbFunctions.TruncateTime(pubdate))
        .Select(AsBookDto);
}
```

The `{pubdate:datetime}` parameter is constrained to match a **DateTime** value. This works, but it's actually more permissive than we'd like. For example, these URIs will also match the route:

`/api/books/date/Thu, 01 May 2008`

`/api/books/date/2000-12-16T00:00:00`

There's nothing wrong with allowing these URIs. However, you can restrict the route to a particular format by adding a regular-expression constraint to the route template:

```
[Route("date/{pubdate:datetime:regex(\\d{4}-\\d{2}-\\d{2})}")]
public IQueryable<BookDto> GetBooks(DateTime pubdate)
{
    // ...
}
```

Now only dates in the form "yyyy-mm-dd" will match. Notice that we don't use the regex to validate that we got a real date. That is handled when Web API tries to convert the URI segment into a **DateTime** instance. An invalid date such as '2012-47-99' will fail to be converted, and the client will get a 404 error.

You can also support a slash separator (`/api/books/date/yyyy/mm/dd`) by adding another **[Route]** attribute with a different regex.

```
[Route("date/{pubdate:datetime:regex(\\d{4}-\\d{2}-\\d{2})}")]
[Route("date/{*pubdate:datetime:regex(\\d{4}/\\d{2}/\\d{2})}")]  // new
public IQueryable<BookDto> GetBooks(DateTime pubdate)
{
    // ...
}
```

There is a subtle but important detail here. The second route template has a wildcard character (*) at the start of the {pubdate} parameter:

```
{*pubdate: ... }
```

This tells the routing engine that {pubdate} should match the rest of the URI. By default, a template parameter matches a single URI segment. In this case, we want {pubdate} to span several URI segments:

`/api/books/date/2013/06/17`

Controller Code

Here is the complete code for the BooksController class.

```
using BooksAPI.DTOs;
using BooksAPI.Models;
using System;
using System.Data.Entity;
using System.Linq;
using System.Linq.Expressions;
using System.Threading.Tasks;
using System.Web.Http;
using System.Web.Http.Description;

namespace BooksAPI.Controllers
{
    [RoutePrefix("api/books")]
    public class BooksController : ApiController
    {
        private BooksAPIContext db = new BooksAPIContext();

        // Typed lambda expression for Select() method.
        private static readonly Expression<Func<Book, BookDto>> AsBookDto =
            x => new BookDto
            {
                Title = x.Title,
                Author = x.Author.Name,
                Genre = x.Genre
            };
```

```
        // GET api/Books
        [Route("")]
        public IQueryable<BookDto> GetBooks()
        {
            return db.Books.Include(b => b.Author).Select(AsBookDto);
        }

        // GET api/Books/5
        [Route("{id:int}")]
        [ResponseType(typeof(BookDto))]
        public async Task<IHttpActionResult> GetBook(int id)
        {
            BookDto book = await db.Books.Include(b => b.Author)
                .Where(b => b.BookId == id)
                .Select(AsBookDto)
                .FirstOrDefaultAsync();
            if (book == null)
            {
                return NotFound();
            }

            return Ok(book);
        }
